mipro 2012

organizer upro

35th international convention

May 21-25, 2012, Opatija - Adriatic Coast, Croatia

with mipro to knowledge society

Lampadem tradere

mipro proceedings

My profession.
My organization.
My IEEE.

Discover the benefits of IEEE membership.

Join a community of more than 365,000 innovators in over 150 countries. IEEE is the world's largest technical society, providing members with access to the latest technical information and research, global networking and career opportunities, and exclusive discounts on education and insurance products.

IEEE

MIPRO 2012

Jubilee 35th International Convention

May 21 - 25, 2012
Opatija, Croatia

Proceedings

Conferences:

Microelectronics, Electronics and Electronic Technology /MEET

Distributed Computing and Visualization Systems /DC-VIS

Telecommunications & Information /CTI

Computers in Technical Systems /CTS

Intelligent Systems /CIS

Computers in Education /CE

Digital Economy - 9th ALADIN /DE

Information Systems Security /ISS

Business Intelligence Systems /miproBIS

Government, Local Government, Public Services /GLGPS

MIPRO Junior - Student Papers /SP

Edited by:
Petar Biljanović

International Program Committee

Petar Biljanović, President, Croatia
A. Abelló Gamazo, Spain
S. Amon, Slovenia
M.E. Auer, Austria
M. Baranović, Croatia
L. Bellatreche, France
N. Bogunović, Croatia
A. Budin, Croatia
Ž. Butković, Croatia
Ž. Car, Croatia
M. Colnarič, Slovenia
A. Cuzzocrea, Italy
M. Čičin-Šain, Croatia
D. Čišić, Croatia
T. Eavis, Canada
M. Ferrari, Italy

CONTENTS

LIST OF PAPER REVIEWERS ..... **XXXIII**

LIST OF AUTORS ..... **XXXV**

FOREWORD ..... **XLIII**

MICROELECTRONICS, ELECTRONICS AND ELECTRONIC TECHNOLOGY

INVITED PAPERS **3**

Erbium Doped Silica Microspheres for Lasing Applications **5**
D. Ristić, L. Lunelli, A. Chiasera, P. Feron, G. Cibiel, M. Ivanda, G. Righini, M. Ferrari

Synthesis Flow for Designing a High Performance Microprocessor **9**
B. Malnar

PAPERS **17**

Porous Silicon Prepared by Electrochemical Etching of Silicon Eptaxial Layer **19**
M. Ivanda, M. Balarin, O. Gamulin, V. Đerek, D. Ristić, S. Musić, M. Ristić, K. Furić, Z. Crnjak Orel

Formation and Luminescence of P-type Porous Polycrystalline Silicon **21**
V. Đerek, M. Ivanda, M. Balarin, O. Gamulin, M. Ristić, S. Musić, K. Furić, Z. Crnjak Orel

Role of the Substrate and the Temperature of Deposition on the Properties of the Ta_xN Thin Films **23**
M. Očko, S. Žonja, M. Ivanda

On the Application of Boron and Phosphorus Heavily Doped LPCVD Polycrystalline Silicon Thin Films as Thermoelectric Materials **25**
S. Žonja, M. Očko, M. Ivanda, T. Suligoj, P. Biljanović

Room Temperature Visible Luminescence in Wide Band Gap Chalcogenide Glasses **27**
V.M. Mitsa, R.M. Holomb, G. Lovas, M. Ivanda, G.Yu. Rudyko, E.G. Gule, I.V. Fekeshgazi

Preparation and Research in Resistive-Strain Sensor Based on Transparent Conducting Graphene Sheets **29**
A.S. Berdinsky, I.A. Reshetnyak, J.B. Yoo, E.D. Grayfer, V.G. Makotchenko, V.E. Fedorov

Study of Electronic Structures of MoX_2 (X = S, Se, Te): Arguments for Interactions of Molybdenum Atoms in Layers **31**
V.E. Fedorov, I.V. Mirzaeva, S.G. Kozlova, E.D. Grayfer, M.V. Medvedev

Investigation of Memory Effect by Measurement of Time Delay of Electrical Breakdown in Commercial Gas filled Surge Arresters **33**
M.M. Pejović, N.T. Nešić, M.M. Pejović, N.J. Bogdanović

RADFET as a Sensor and Dosimeter of Gamma-Ray Irradiation 37
M.M. Pejović, M.M. Pejović, N.T. Nešić

Modelling of Electrical Characteristics of Ultrashallow Pure Amorphous Boron p+n Junctions 42
T. Knežević, T. Suligoj, A. Šakić, L.K. Nanver

Model Optimization of Nanocrystalline Si:H Thin Film Solar Cells 48
V. Tudić, Lj. Majdandžić, J. Groš

Measurement of Thermal Boundary Resistance in AlGaN/GaN HEMTs Using Liquid Crystal Thermography 54
D. Babić, Q. Diduck, J. Smart, D. Francis, F. Faili, F. Ejeckam

Design of a Planar Inductor for DC-DC Converter on Flexible Foil Applications 60
J. Kundrata, A. Barić

Development of an Analog Simulator for the Transient Analysis of Electric Circuits, with the Aim of Teaching Circuit Phenomena by Simulating Equations 66
M. Jenko

A Fast and Accurate Simulation Method of Impulse Sensitivity Function in Oscillators 72
F. Pepe, A. Bonfanti, A. Lacaita

A Brief Overview of the Black-Box Behavioural Modelling of Electronic Circuits for Transient Simulations 78
V. Čeperić, A. Barić

A 2.5-GHz GaN Power Amplifier Design and Modeling by Circuit-Electromagnetic Co-Simulation 84
A. Broznić, R. Blečić, A. Barić

Pseudo-Exponential Computational Circuit with Improved Accuracy and Frequency Response 89
C. Popa

The Simple CMOS Negative Capacitance with Improved Frequency Response 93
B. Mrković, M. Ašenbrener

Impact of Bipolar Transistor Parameters on the Characteristics of the Double-Balanced Mixer 97
J. Žilak, M. Koričić, T. Suligoj

Logic Circuits with High-Impedance Output State for Interconnection of Ternary and Binary CMOS Digital Circuits and Systems 103
D. Bundalo, Z. Bundalo, F. Softić, M. Kostadinović, D. Pašalić

Limitations of the CVSL Driver as Voltage Level Booster for Switching Capacitors in High-Gain Charge Pumps 109
D. Vinko, T. Švedek, A. Barić

Intelligent Power MOSFET Driver ASIC 113
J. Podržaj, A. Sešek, J. Trontelj

Reconfigurable Processor Architectures: Varieties and Representations.....118
D. Kirasić, D. Basch

A Novel Solution for Realisation of Data Transfer in Borehole Measurement Systems.....124
V. Dogan, M. Brkić, N. Vukoje, G. Mančić, M.B. Živanov

Design of CIC Compensators with SPT Coefficients Based on Interval Analysis.....129
M. Glavinić Pecotić, G. Molnar, M. Vučić

Method for Selection of Switches for Power Electronic Converters.....135
I. Mrčela, V. Šunde, Z. Benčić

Simple Control System for Power Converter Connecting Electrochemical Dual-Layer Capacitors to DC Link.....141
T. Čihak, Ž. Jakopović

Wireless Power Transfer for Mobile Phone Charging Device 147
L. Olvitz, D. Vinko, T. Švedek

Hardware Realization of Autonomous Robot Localization System 152
M. Brkić, M. Lukić, J. Bajić, B. Dakić, M. Vukadinović

Development of Cost-Effective Redundant Digital Excitation Control.....157
H. Lee, H. Ryu, J. Kwon, G. Park, I. Kim, H. Kim

A Fully Integrated Multicolor Photoreceiver 162
J. Dong, W. Gaberl, K. Schneider-Hornstein, H. Zimmermann

The Frequency-Modulated Reflective Color Sensor 168
J.S. Bajić, B. Dakić, D.Z. Stupar, M.P. Slankamenac, M.B. Živanov

Implementation of the Optical Beam Profiler System Using LabVIEW Software Package and Low-Cost Web Camera 173
J.S. Bajić, D.Z. Stupar, J. Tomić, M.P. Slankamenac, A. Joža, M.B. Živanov

Performance Analysis of a Tunable Piezoelectric Actuator Based MEMS Resonator 179
R. Resmi, M.R. Baiju

Chipless Wireless Sensor Node.....185
S. Preradović, A. Meničanin

System for Monitoring Concentration of NO_2 and CO Gasses on Landfill Sites 189
Ž. Mihajlović, V. Milosavljević, N. Maoduš, V. Rajs, M.P. Slankamenac, M.B. Živanov

A Positive Study on Effective Gas Safety Management Using Wireless Sensor Network 193
G.T. Park, Y.G. Kim, I.C. Kim, H.S. Kim

Availability and Reilability of FSO Links Estimation from Measured Fog Parameters.....198
M. Tatarko, L'. Ovseník, J. Turán

Disadvantages of Methods for Power Indication during Treadmill Exercise for Ergospirometry Test 202
A. Badnjević, E. Beganović, G. Šehić, A. Badnjević

Estimation of Muscle Fatigue during Dynamic Contractions Based on Surface Electromyography and Accelerometry **207**
M. Jordanić, R. Magjarević

Biomechanical Scale for Dynamic Human Body Posture Analysis **212**
M. Cifrek, S. Peharec, H. Džapo, T. Pribanić, S. Mrvoš

High Quality Hearing Aids **217**
J. Ostojić, M. Krhen, B. Somek, V. Pinezić

USB RF Front-End of the DRM Receiver under LabView API Environment **224**
D. Šoštarić, D. Vinko, T. Švedek

Verification Structures for Design of Video Processing Circuits **228**
A. Trošt, A. Žemva

Computational Study on Soliton-like Pulses in the Nonlinear RLC Transmission Lines **234**
D.L. Sekulić, M.B. Živanov

Ink-jet Printed CPW Inductors in Flexible Technology **239**
A. Meničanin, Lj. Živanov, M. Damnjanović, A. Marić, N. Samardžić

Universal Wireless Communication Detector (UD-100) - Preventing of High-Tech Cheating Methods **243**
J.S. Bajić, V. Milosavljević, V. Rajs, M.P. Slankamenac, M.B. Živanov

Investigation of Electrically Small Monofilar Spherical Helical Antenna Used for Mid-Range Wireless Power Transfer **247**
M. Škiljo, Z. Blažević

DISTRIBUTED COMPUTING AND VISUALIZATION SYSTEMS

PAPERS **257**

DISTRIBUTED COMPUTING

Green HPC: MPI vs. OpenMP on a Shared Memory System **259**
Z. Krpić, G. Martinović, I. Crnković

Matrix Multiplication Performance Analysis in Virtualized Shared Memory Multiprocessor **264**
M. Gusev, S. Ristov

Preventing State Divergence in Duplex Systems Using Causal Memory **270**
B. Chitsaz, M. Razzazi

An Improved Approach to Track Forest Fires and to Predict the Spread Direction with WSNs Using Mobile Agents **275**
I. Vukasinović, G. Rakočević

Monitoring UNICORE Jobs Executed on Desktop Grid Resources **278**
J. Kovacs, F. Araujo, S. Boychenko, M. Keller, A. Brinkmann

Transparent Execution of ARC Jobs on Desktop Grid Resources **284**
C.U. Soettrup, A. Wäänänen, J. Kovacs

Agent-Based Topology Control for Wireless Sensor Network Applications **290**
D. Rojković, T. Crnić, I. Čavrak

Security in Distributed Wireless Sensor Networks **296**
T. Petrović, M. Žagar

Evolution and Trends in GPU Computing **302**
M.J. Mišić, Đ.M. Đurđević, M.V. Tomašević

Application Repository Based Evaluation of the EDGI Infrastructure **308**
A. Visegradi, S. Acs, J. Kovacs, G. Terstyanszky

Multicluster Hadoop Distributed File System **314**
I. Tomašić, J. Ugovšek, A. Rashkovska, R. Trobec

AbacusFS Integrated Storage and Computational Platform **319**
I. Nuhić, M. Šterk, T. Cortes

Tool Orchestration Framework for Virtual Team Environments **326**
A. Martinić, K. Fertalj, D. Kalpić

Comparative NAMD Benchmarking on BlueGene/P **332**
A.H. Poghosyan, L.H. Arsenyan , H.V. Astsatryan

DISTRIBUTED PROGRAMMING AND CLOUD SERVICE

Accessing and Steering the Elastic OLAP Cloud **337**
S. Ye, P. Chen, I. Janciak, P. Brezany

ECM Integer Factorization on GPU Cluster **343**
E. Atanassov, D. Georgiev, N.L. Manev

An I/O Cost Optimal and Progressive Algorithm for Computing Massive Skyline Points **348**
M. Talebi, M. Razzazi

Non-Blocking Roll-Forward Recovery for Message Passing Systems **354**
B. Chitsaz, M. Razzazi

Non-Blocking N-Version Programming for Message Passing Systems **360**
B. Chitsaz, M. Razzazi

A Cellular Automata Based Algorithm for Voronoi Diagram of Arbitrary Shapes **364**
M. Talebi, A. Mohammadalimaddi, M. Razzazi

Parallel Implementation of a Combustion Chamber Simulation with MPI-OpenMP Hybrid Techniques **371**
L. Környei

FPGA Implementations of Data Mining Algorithms **377**
P. Škoda, B. Medved Rogina, V. Sruk

Parallel Implementation of Option Pricing Methods on Multiple GPUs 383
E. Atanassov, S. Ivanovska, D. Dimitrov

Analysing User Click Paths in a Wikipedia Navigation Game 389
D. Helić

Models for the Development of Web Service Orchestrations.....395
J. Matković, K. Fertalj

Superlinear Speedup in OpenMP Parallelization of a Local PDE Solver.....404
G. Kosec, M. Depolli

Simulated Annealing and Variable Neighborhood Search Algorithm for Automated Software Services Composition 410
V. Giedrimas, L. Sakalauskas

Running High Performance Linpack on CPUGPU Clusters 415
D. Tomić, D. Ogrizović

The Segmentation of Data Set Area Method in the Clustering of Uncertain Data 420
I. Lukić, M. Köhler, N. Slavek

Bridging the Gaps: Federation of Clouds Using Grid Services and Standards.....426
S. Memon, J. Rybicki, M. Riedel, S. Memon, E. Yen

Security Issues of the Combined Usage of Grid and Cloud Resources 432
E. Atanassov, T. Gurov, A. Karaivanova

Framework for Implementation of Complex Dynamic Web Forms.....436
K. Kroflin, S. Prstačić, M. Žagar

Interfaces of Nested Web Application Framework as Reusable Software Component.....439
S. Prstačić, M. Žagar, K. Kroflin

Maxwell's Equations for Nanotechnology.....444
M. Perkovac

CloudMan as a Tool Execution Framework for the Cloud 452
E. Afgan, K. Skala, D. Davidović, T. Lipić, I. Sović

BIOINFORMATICS, MEDICINE AND VISUALIZATION

Short Fragment Sequence Alignment on the HP-SEE Infrastructure 459
M. Kozlovszky, G. Windisch, Á. Balaskó

Remote Monitoring of Vital Functions - Proof-of-Concept System.....463
A. Rashkovska, I. Tomašić, K. Bregar, R. Trobec

A Distributed Clinical Information System for Pediatric Surgery - Basics and Specifics.....468
D.L. Petrova, G. Spasov, P. Stefanova-Peeva

Modeling and Analysis of the Gateway Node in Body Sensor Networks 474
M.P. Shopov, G.V. Spasov, G.I. Petrova

Coarse Grain Simulation and Visualisation of Lipid and Water Molecules Ensembles 479
J.I. Pavlič, R. Trobec

What is the Destiny of Information Science Doctors?.....484
Đ. Pečarić

Auditory Display of Biomedical Signals through a Sonic Representation: ECG and EEG Sonification 491
V. Avbelj

Video Driver Assistance System Using Optical Correlator 493
T. Harasthy, L'. Ovseník, J. Turán

Integration of Skype Client and Performance Analysts on Television Platform.....496
D. Živkov, M. Davidović, M. Vidović, N. Žmukić, A. Anđelković

A Visualization and User Interface Framework for Heterogeneous Distributed Environments.....500
M. Mahnič, D. Skočaj

K-Means Image Segmentation on Massively Parallel GPU Architecture.....506
J. Sirotković, H. Dujmić, V. Papić

TELECOMMUNICATIONS AND INFORMATION

PAPERS 517

CLOUD COMPUTING IN TELECOMMUNICATIONS

Opportunities for Telecom Operators in Cloud Computing Business 519
N. Katica, A. Tahirović

The Use of IMS for Cloud Based Services Control and Management.....525
V. Čačković, Ž. Popović

Possible Scenarios for Cloud-Based Offering by Operators 530
S. Počuča, B. Maršić, A. Grgić

REST-Style Actionscript Programming Interface for Message Distribution Using Amazon Simple Queue Service.....536
K. Popović, Ž. Hocenski

TELECOMM BUSINESS MANAGEMENT

Result of Using Formal Methods in Modeling Telecommunication Business Management 543
D. Markulin, M. Kunštić

Proposal for Business Process Modelling and Development in Condition of Complex Telecommunication Market 549
K. Musa, D. Markulin

Evaluation of a Development Framework for a Mobile Gaming Platform with Financial Transfers 554
R. Hable, E. Platzer

Wireless Connecting of Substations for the Purposes of Business and Process Networks of HEP 560
I. Fosić, V. Ećimović

Istraživanje o preferencijama i očekivanjima hrvatskih IPTV korisnika 564
B. Jukić

NETWORK MANAGEMENT

An Optimum Scheme for WiMAX Bandwidth Management Using Dynamic Channel Allocation 573
M.F. Al-Mistarihi, M.Y. Mowafi, M.S. Marei

Methodology for Optimal Link Selection Using Multivariant Normal Distribution 577
M. Hruby, M. Olsovsky, M. Kotočová

A Dual Usage of Cognitive Radio in Managing the WiMAX Bandwidth 583
M.Y. Mowafi, M.F. Al-Mistarihi, M.S. Marei

Comparison Ways of Assignment of Codes in UMTS Networks 587
S. Kasapović, S. Mujačić, D. Čeke, A. Hadžimehmedović

One Approach to the Development of Custom SNMP Agents and Integration with Management Systems 592
T. Kazaz, M. Kulin, E. Kaljić, T. Čaršimanović

Implementacija sustava za dinamičku prilagodbu karakteristika DSL linija u okruženju telekomunikacijskog operatora 597
D. Butković, N. Dragun

OPTICAL NETWORKS

Optimal Techno-Economic Selection of the Optical Access Network Topologies 607
Ž. Božinović, H. Dizdarević, S. Dizdarević

Availability of All-Optical Switching Fabrics Used in Optical Cross-Connects 613
M. Džanko, B. Mikac, V. Miletić

Otvoreni pristup korištenju FTTH aktivne opreme 618
S. Horvat, I. Barešić, Z. Trlin

REGULATIONS AND STANDARDIZATION

Pravno uređenje nadzora i tehničko snimanje telekomunikacija u državama Europske unije i Bosni i Hercegovini 627
F. Gabela

Pravni okvir primjene elektronskih potpisa u Bosni i Hercegovini 633
H. Šemić, F. Gabela

Regulatorni aspekti internetske televizije 640
I. Kasipović, I. Podnar Žarko

An Approach to Estimate Correlation between QoS and Perceptual Video Quality in Packet-Switched Networks 646
J. Zečić, M. Hadžialić, A. Hasković

Regulatorni aspekti kognitivnog radio pristupa....652
A. Džebo, H. Mutapčić

Access Regulatory Remedies in Point-to-Multipoint Fiber Access Networks....657
T. Majnarić

SIGNALING AND PROTOCOLS

Improvement of Method for Telephony Network Signal Sending over Internet 665
A. Lebl, Ž. Markov, D. Mitić

Impact of Non-Service Related Signaling in GSM Mobile Networks....669
M. Skomeršić, T. Gojević, M. Žuvanić

Implementacija IPv6 na OSPF usmjernički protokol....673
D. Žigman, I. Jesih, N. Kasunić

Implementation of Parlay X Interfaces for Standard GSM Modems to Support the Development of SMS-Based Applications....677
E. Kaljić, M. Hadžialić, M. Kurić

NgP Protokol za dogovor parametara....682
S. Brčina, L. Kovačević, M. Marić, M. Mikuc, T. Marini, V. Pokornić, V. Vasić, R. Vežnaver

SMART TELECOMM PLATFORMS

Smart Automated Platform for Telecom Operators and Enterprise Users in Industry, Transport and Energy....689
D. Peraković, Z. Kljaić, S. Štefičar

The "Horizontalization" of the Machine to Machine (M2M) World and How to Market It....694
A. Metnitzer

Machine to Machine (M2M) Communication Impacts on Mobile Network Capacity and Behaviour....698
S. Počuča, D. Giljević

BFriend: Contex-Aware Ad-Hoc Social Networking for Mobile Users 703
V. Smailović, V. Podobnik

Monitoring and Analysis of Player Behavior in World of Warcraft....709
M. Sužnjević, M. Matijašević, B. Brozović

KNOWLEDGE MANAGEMENT

Social Analytics for Mobile Operators 717
M. Poldrugač, M. Komadina

The Challenge of Customer Experience Management 722
D.Tučkar

Knowledge Granulation in a Telecom Operator Information Systems 728
N. Dragun

Computer Aided Competence Management 734
I. Ćubić, N. Pivac, G. Škugor

Preporučivanje novinskih članaka hibridnim pristupom 740
K. Rožanković, I. Podnar Žarko

NETWORK PERFORMANCE

Performance Analysis of Multiuser Diversity in Multiuser Two-Hop Amplify and Forward Cooperative Multi-Relay Wireless Networks 749
M.F. Al-Mistarihi, A. Sharaqa, R. Mohaisen, O. Abu-Alnadi, H. Abu-Seba

Impact of Frequency Synchronization on QoS in IP Based Networks 754
M. Hadžialić, M. Džaferagić, D. Rača

Quality of Service Mechanisms and Priority Management in HSPA System 758
I. Medvid, M. Mikuc

Analiza kvalitete IMS VoIP servisa na osnovu izmjerenih QoS parametara 764
A. Hota, B. Puškarević

Iskustvena kvaliteta video sadržaja za usluge u pokretnoj mreži treće generacije 770
D. Vučić, I. Medvid

A Multi-Dimensional View of QoE - the ARCU Model 775
L. Skorin-Kapov, M. Varela

An IP Based Security Threat in Mobile Networks 780
M. Nagy, M. Kotočová

Mobile Network Protection System against Fraudulent and Unwanted Messaging Traffic 784
T. Gojević, K. Matas, M. Skomeršić, M. Žuvanić

Denial of Service (DoS) Attacks in Green Mobile Ad-Hoc Networks 788
A. Kanthe, D. Šimunić, M. Đurek

Analyses and Optimisation of ADSL/VDSL Lines Using Ericsson APM System – Comparing Results of Two Operators 794
A. Kerner, P. Cota

SOFTWARE ENGINEERING

Archetypes Based Development from the Perspective of Domain Engineering Research Topics **801**
J. Tepandi, G. Piho, V. Puusep

Agile Experiences in Software Development **807**
D. Duka

Multivariate Logistic Regression Prediction of Fault-proneness in Software Modules **813**
G. Mauša, T. Galinac Grbac, B. Dalbelo Bašić

SERVICES

Integration of Hosting Service into Triple Play Service of Telecom Operator **821**
A. Tanović, F. Oručević

Telecom Services Self-Care Portal for Business Customers **827**
K. Rebernak, M. Botinčan, D. Šarić

Udaljena pohrana podataka korištenjem slobodnog softvera **832**
B. Radojević, M. Nalis, V. Vidić, S. Čavara

Uloga pristupne točke javne sigurnosti u telekomunikacijskoj usluzi ePoziv **836**
P. Britvić, H. Strepački

NEW TELECOMM APPLICATIONS

Evaluating a Medical Grade Network through Network Calculus **841**
N.R. Kakanakov

Towards LIMS (Laboratory Information Management Systems) Software in Global Context **847**
G. Piho, J. Tepandi, M. Parman

Active Wireless Sensor with Radio Frequency Identification Chip **853**
D. Ćika, M. Draganić, Z. Šipuš

IP Multimedia Subsystem (IMS) sigurnost: Pregled standardizacije IMS sigurnosti i potencijalnih prijetnji na sistem **859**
B. Puškarević, A. Hota

GREEN ICT

Fundamental Optimization Criteria for Green Wireless Communications **869**
M. Pejanović-Đurišić, E. Stovrag, M. Ilić-Delibašić

Performance Analysis of Covariance Based Detection in Cognitive Radio **873**
T. Dhope, D. Šimunić

Benchmarking Performance and Energy Efficiency of Microprocessors for Wireless Sensor Network Applications **879**
U. Pešović, Z. Jovanović, S. Ranđić, D. Marković

Using Radio Irregularity for Vehicle Detection in Adaptive Roadway Lighting 884
G. Horvat, D. Šoštarić, D. Žagar

Energy Consumption in Android Phones when Using Wireless Communication Technologies.....890
G. Kalić, I. Bojić, M. Kušek

Power Line Communication System Modeling Based on Coded OFDM.....896
M. Bogdanović

Hybrid Detection Method for Spectrum Sensing in Cognitive Radio 901
D. Šimunić, T. Dhope

A Solution for BER Performance and Energy Efficiency Improvements of OFDM-CDMA System with Pilot Tone.....907
U. Urošević, Z. Veljović, M. Pejanović-Đurišić

Wireless InSite Software Verification via Analysis and Comparison of Simulation and Measurement Results.....912

INTELLIGENT SYSTEMS

PAPERS 1137

Ultrasound Medical Image Recognition with Artificial Intelligence for Parkinson's Disease Classification 1139
J. Blahuta, T. Soukup, P. Čermák, J. Rozsypal, M. Večerek

Neural Network-Based Digital Map Extraction Approach **1144**
S. Tulyakov, D. Vyleghzanin, R. Sadykhov

Personal Recognition Based on the Gabor Features of Colour Palmprint Images **1148**
S. Ribarić, M. Marčetić

Curve Similarity Measurement Algorithms for Automatic Gesture Detection Systems **1154**
V. Shehu, A. Dika

Estimating OD Matrices at Intersections in Airborne Video - a Pilot Study **1158**
V. Braut, M. Čuljak, V. Vukotić, S. Šegvić, M. Ševrović, H. Gold

Comparison between Initial Skew Rate and Moment Based Method for the Printed Text Skew Estimation **1164**
D. Brodić, D.R. Milivojević, B. Dokić, V. Tasić

Croatian Visual Speech Synthesis **1168**
M. Pobar, I. Ipšić

Continuity of Approximate Reasoning Using Center of Sums Defuzzification Method **1172**
T. Mitsuishi

Comparison of Algorithms for Patent Documents Clusterization **1176**
D. Kukolj, Ž. Tekić, Lj. Nikolić, Z. Panjkov, M. Pokrić, M. Dražić, M. Vitas, D. Nemet

Deep Learning Architecture for Data Mining from Surgical Data **1179**
I. Nikolova

Towards Semantic and Affective Coupling in Emotionally Annotated Databases **1184**
M. Horvat, S. Popović, K. Ćosić

Virtual Social Multimedia Streaming with a Novel Haptic Device **1190**
M. Gaudina, A. Brogni, M. Migliardi, D. Caldwell

Novel Approaches to Automated Personality Classification: Ideas and Their Potentials **1198**
A. Kartelj, V. Filipović, V. Milutinović

Fast Feature Reduction in Intrusion Detection Datasets **1204**
S. Parsazad, E. Saboori, A. Allahyar

Topic Models and Advanced Algorithms for Profiling of Knowledge in Scientific Papers **1211**
V. Jelisavčić, B. Furlan, J. Protić, V. Milutinović

Etalon-Based Integrated Microchip Inspection System **1217**
S. Tulyakov, I. Radchanka, S. Basalayev, R. Sadykhov

Wavelet Analysis of Hydrological Signals on an Example of the River Sava **1223**
A. Sović, K. Potočki, D. Seršić, N. Kuspilić

Sound of Boiling as a Disturbing Noise and as a Functional Signal **1229**
A. Smrke, J. Prezelj, P. Šteblaj, I. Smrke

Parallel Neural Network Training with OpenCL **1234**
N. Krpan, D. Jakobović

Application of Genetic Algorithms in Wire Busbars Design 1239
D. Petranović

On the Analysis of Experimental Results in Evolutionary Computation 1245
S. Picek, M. Golub, D. Jakobović

Stadium Reflector Aiming Using Genetic Algorithms 1251
D. Petranović

Towards Software Autogeneration 1257
D. Radošević, T. Orehovački, I. Magdalenić

New Transformation Approach for Model Driven Architecture 1263
E.A. Cherkashin, I.N. Terehin, V.V. Paramonov, V.S. Tertychniy

Extraction of Thesaurus and Project Structure from Linux Kernel Source Tree 1269
A.Y. Sokolov, I.R. Golovko, E.A. Cherkashin

A Review of Iterated Prisoner's Dilemma Strategies 1274
M. Jurišić, D. Kermek, M. Konecki

A Model of Software System for Parking Using Search Algorithms 1279
D. Drašković, S. Vukićević

A Two-Phase Vehicle Based Decomposition Algorithm for Large-Scale Capacitated Vehicle Routing with Time Windows 1285
M. Gulić, D. Lučanin, N. Skorin-Kapov

Implementation of Tracking Mobile Application and Analysis of Spatial Data 1290
D. Donko, A. Alispahić

COMPUTERS IN EDUCATION

PAPERS 1297

Laboratory Exercises for Embedded Engineering Learning Platform 1299
I. Kaštelan, D. Majstorović, M. Nikolić, J. Eremić, M. Katona

Assessment of e-Learning Materials Aestetic Design 1304
M. Duh, B. Bedrač, M. Krašna

Automating the Formal Logic Course 1310
G. Molnar, V. Omrčen, M. Čupić

Croatian Libraries on Facebook – Content Analysis 1316
M. Banek Zorica, T. Ivanjko, M. Benčec

Personal Learning Environments: The Implication on Process of e-Learning 1321
Ž. Požgaj, V. Bosilj Vukšić

Developing the Course Database Systems to Respond to Market Requirements 1327
P. Poščić, D. Subotić, M. Ivašić-Kos

ViSA: Visualization of Sorting Algorithms **1332**
I. Reif, T. Orehovački

An Innovative Industrial Automation System Showcase for Quality Management and Statistical Process Control Lectures **1338**
C. Madritsch, C. Ungermanns, T. Klinger, W. Werth

Cultural Influence on the Intellectual Honesty and Fairness of the German and Croatian Students **1342**
D. Lukač, M. Čičin-Šain

Education via Modeling and Simulation **1347**
L. Révészová

Role of ICT in Learning and Knowledge Acquisition: How Much Students Know about Their Research Skills? **1352**
J. Lovrinčević, D. Kovačević, M. Erl Šafar

E-Learning as a Tool for Improving ICT Knowledge of University Teachers **1358**

MIPRO Junior - STUDENT PAPERS

PAPERS 2103

Djeluje li laskanje? O utjecaju snage poruke i pripisivanja identiteta altruistične osobe na odaziv sudionika u istraživanju putem interneta 2105
J. Okroša

Razvoj modela e-škole kao dodatnog oblika nastave za djecu koja žive izvan Hrvatske 2110
T. Težak, M. Dumančić

Tehnički i socijalni pogledi na web forume, na primjeru foruma TVZ-a 2115
L. Tepeš Golubić, J. Kolarec

A Method for Real-Time Detection of Human Fall from Video 2121
M. Kreković, P. Čerić, T. Dominko, M. Ilijaš, K. Ivančić, V. Skolan, J. Šarlija

LightDesk - sustav za računalnu interakciju visoke rezolucije baziran na infracrvenom raspoznavanju oblika 2125
A. Divjak, M. Maričević

Detection of Commercials in Video Content Based on Logo Presence without Its Prior Knowledge 2130
N. Banić

User Authentication Based on Keystroke Dynamics Analysis 2136
I. Sluganović, A. Karlović, P. Bosilj, M. Šare, S. Horvat

A Brief Introduction to OpenCV 2142
I. Čuljak, D. Abram, T. Pribanić, H. Džapo, M. Cifrek

Implementation of Algorithm for Detection and Correction of Defective Pixels in FPGA 2148
L. Mijatović, H. Dean, M. Rožić

Emocionalni dizajn: važnost emocija u procesu izrade web stranica 2153
I. Grbavac, N. Marangunić, A. Granić

Image-Based Visual Servoing for Automatic Control of Balancing Beam 2159
S. Marković, J. Musić, M. Bonković

Scaling Read-Heavy Web Services 2165
E. Dedović, J. Balagija, N. Čavrk, N. Nosović

Design and Implementation of Fuzzy Controller on Embedded Computer for Water Level Control 2170
S. Krivić, M. Hujdur, A. Mrzić, S. Konjicija

The Procedure of a Camera Calibration Using Camera Calibration Toolbox for MATLAB 2175
A. Fetić, D. Jurić, D. Osmanković

A Hybrid Ant Colony System Approach for Solving Capacitated Vehicle Routing Problems with Time Windows 2181
F. Boltužić, A. Rakipović

Android Application for Sending SMS Messages with Speech Recognition Interface 2186
S. Primorac, M. Russo

A Robust Hand Detection and Tracking Algorithm with Application to Natural User Interface 2191
T. Benussi, D. Jurić

Recommendation of YouTube Videos 2198
M. Brbić, E. Rožić, I. Podnar Žarko

A Comparison of Five Parallel Programming Models for C++ 2203
E. Ajkunić, H. Fatkić, E. Omerović, K. Talić, N. Nosović

Performance Comparison of Simulated Annealing Algorithm Execution on GPU and CPU 2208
E. Bajrami, M. Ašić, E. Cogo, D. Trnka, N. Nosović

Parallelization of Array Operations by Using Socket Programming in .NET 2212
E. Kurtanović, E. Meholjić, N. Hadžić, B. Davidović, E. Ljevaković, N. Nosović

Tiled 360º Panoramic Projection System 2216
D. Hrenek, I. Kušt, N. Mikša, P. Prentašić, B. Trubić, A. Heđi, S. Lončarić, M. Subašić

Multi-Camera Person Tracking System 2221
D. Komlen, T. Lombarović, M. Ogrizek-Tomaš, D. Petek, A. Petković

Artificial Neural Network Based Stock Value Prediction 2226
D. Hrenek, N. Mikša, P. Prentašić, B. Trubić

CUDA Implementation of the Algorithm for Simulating the Epidemic Spreading over Large Networks 2230
M. Šošić, M. Šikić

Dijkstra's Shortest Path Algorithm Serial and Parallel Execution Performance Analysis 2234
N. Jasika, N. Alispahić, E. Arslanagić, I. Kurtović, E. Lagumdžija, N. Nosović

FOREWORD

The *Jubilee 35th International ICT Convention MIPRO 2012* was held from 21st until 25th of May 2012 in Opatija, the Adriatic Coast, Croatia. The Convention consisted of ten conferences under the titles: *Microelectronics, Electronics and Electronic Technology (MEET), Distributed Computing and Visualization Systems (DC-VIS), Telecommunications & Information (CTI), Computers in Technical Systems (CTS), Intelligent Systems (CIS), Computers in Education (CE), Digital Economy (DE), Information Systems Security (ISS), Business Intelligence Systems (miproBIS), Government, Local Government, Public Services (GLGPS)*. A special conference was dedicated to works of the students: *MIPRO Junior-Student Papers (SP)*.

The papers presented on these conferences are contained in this comprehensive Book of Proceedings. All the papers were reviewed by an international review board. The list of reviewers is contained in the Book of Proceedings. All the positively reviewed papers are included in the Book of Proceedings. These papers were written by authors from the industry, scientific institutions, educational institutions, state and local administration.

The convention was organized by the Croatian ICT Association MIPRO with the help of numerous co-organizers, sponsors and patrons to whom we owe our sincere thanks. We specially single out our gold sponsors T-Croatian Telecom, Ericsson Nikola Tesla, Končar-Electrical Industries and HEP–Croatian Electricity Company, and the silver sponsors Nokia Siemens Networks and IBM Croatia. Our bronze sponsors are Siemens, InfoData, OiV, VIPNet and Adnet.

To all who helped organize the 35th International ICT Convention *MIPRO 2012* as well as editing of this Book of Proceedings we extend our heartfelt thanks.

Prof. Petar Biljanović, PhD
International Program Committee Chairman

MEET

International Conference on

MICROELECTRONICS, ELECTRONICS AND ELECTRONIC TECHNOLOGY

Steering Committee

Chairs: Petar Biljanović, University of Zagreb, Croatia
Željko Butković, University of Zagreb, Croatia

Members: Slavko Amon, University of Ljubljana, Slovenia
Dubravko Babić, University of Zagreb, Croatia
Maurizio Ferrari, CNR-IFN, Povo-Trento, Italy
Mile Ivanda, Ruđer Bošković Institute, Zagreb, Croatia
Branimir Pejčinović, Portland State University, USA
Aleksandar Szabo, IEEE Croatia Section
Baldomir Zajc, University of Ljubljana, Slovenia

INVITED PAPERS

Erbium Doped Silica Microspheres for Lasing Applications

Davor Ristić[1], Lorenzo Lunelli[2], Alessandro Chiasera[1], Patrice Feron[3], Gilles Cibiel[4], Mile Ivanda[5], Giancarlo C. Righini[6], Maurizio Ferrari[1]

Abstract - Silica microspheres were made by melting the tip of a standard telecom fiber. They were coated using a dip coating apparatus with a 70% SiO2 – 30 HfO_2 sol-gel derived glass activated by 0.3 % mol of Er^{3+}. The whispering gallery modes of the coated resonator were studied using a full taper – microsphere coupling setup. Upon excitation at 1480 nm sharp peaks in the wavelength range from 1540-1565 nm were observed pertaining to the lasing modes of the microresonator.

I. INTRODUCTION

Silica microresonators are a high quality low-mode volume microresonators. The microspheres can be produced very easily by melting the tip of a standard optical fiber either using a arc discharge or a torch. Inside the microspheres the light is confined by total internal reflection along the circumference of the sphere. The modes of the microsphere are called the whispering gallery modes (WGM)[1]. Their high Q-factor makes them suitable for applications where high light density is required such as lasing applications or non-linear optics. If the microspheres were to be used for lasing applications the optically active material has to be introduced inside the microsphere. This can be done either by producing the entire microsphere from a doped glass or by coating the microsphere with an optically active material. The second method has many advantages over the first since the electric field of the WGMs inside the microspheres is confined close to the surface of the sphere. Different optically active materials can be used for the coating of the microspheres [2-6]. In this paper we present the results about the erbium activated silica-hafnia coated silica microspheres. The silica-hafnia is a very promising material for optical application. It was found to be an excellent host for rare-earth ions. Furthermore it was found that upon annealing at 1000 ^oC hafnia nanocrystals are formed, and that the rare-earth tend to locate themselves around these hafnia nanocrystals greatly increasing their spectroscopic properties such as the emission and absorption cross-section. Detail studies of this material are given elsewhere[7,8].

II. EXPERIMENTAL

The microspheres were produced by melting the tip of a standard optical telecommunications fiber. The diameter of the microsphere was found to be 140±10 μm using a standard optical microscope. The image of the microsphere taken with a optical microscope is given in Figure 1. The microspheres were coated with a film with the composition 70% SiO_2-30% HfO_2 activated with 0.3% mol Er^{3+}. The films were coated using a dip coating technique. The sol was prepared by mixing a solution of $Si(OC_2H_5)_4$ (TEOS), HCl, H_2O, CH_3CH_2OH (ethanol) and $HfOCl_2$. The molar ratio between TEOS, water and the catalyst (HCl) was $n(H_2O) : n(Si(OC_2H_5)_4) : n(HCl) = 200:100:1$. The molar ratio between the TEOS and $HfOCl_2$ was chosen to be $n(Si(OC_2H_5)_4) : n(HfOCl_2) = 70:30$ on the basis of previous experiments. The overall amount of Si and Hf in the sol was controlled so that $c(Si(OC_2H_5)_4) + c(HfOCl_2) = 4.48\ 10^{-4}$ mol/mL in order for the sol to have the viscosity which makes the coating speed to be about 40 nm/dip. Er $(NO_3)_3$ x $5H_2O$ was added to activate the film so that the molar concentration of Er^{3+} in the sol is 0.3 %. The mixture of TEOS, HCl and

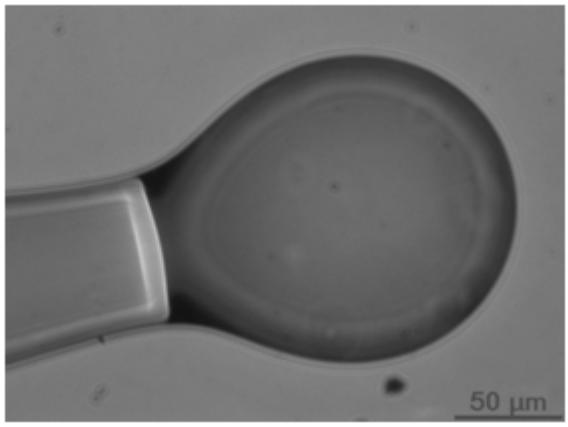

Figure 1. Optical image of the coated microphere

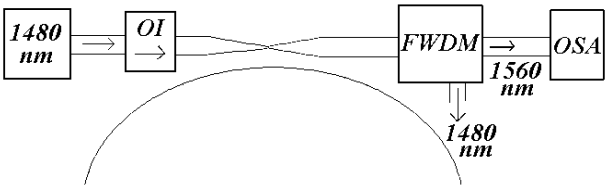

Figure 2. The sketch of the microsphere – taper coupling setup.

H_2O was prehydrolised at 65 ^oC for 1 hour before adding the $HfOCl_2$ and the Er $(NO_3)_3$ x $5H_2O$. The entire mixture was then stirred for 16 h until the sol became transparent. Each microsphere was dipped 30 times into the sol. The dipping speed was 40 mm/min and the dipping time 20s. After each dip the microspheres were densified at 900 ^oC for 50 s and after every 10 dips an additional densification was made for 2 min. At the end of the deposition a final densification for 5 min at 900 ^oC was made. A waveguide sample was also made by coating a silica slide with the same sol used for the coating of one of the microspheres. The thickness of the waveguide was determined by m-line spectroscopy. The far field luminescence was measured by exciting the sample using the 514.5 nm line of a argon-ion laser and by collecting the signal using a InGaS detector.

The measurement of the whispering gallery modes was done using a microsphere-taper coupling setup sketched in Figure 2. A 1480 nm (S-band) fibre diode laser was used for the pumping. The laser was passed through an optical isolator (OI) in order to eliminate the back reflection of the laser. The pump laser was made pass through a tapered fiber with a waist radius less than 2 μm in order to achieve coupling with the microsphere. The coupling is achieved by moving the taper close to the sphere so that the evanescent field of the taper and of the whispering gallery modes of the microsphere overlap. The pump laser is coupled inside the microsphere where it is absorbed by Er^{3+} ions inside the coating which in turn emit in the C-band wavelength region around 1550 nm. The emission will be greatly enhanced at wavelengths which correspond to the WGMs of the microsphere. This emitted light is then coupled out of the sphere and into the taper. A C/S band filter wavelength division multiplexer (FWDM) was used to filter out the S-band 1480 nm pump line and to pass through to the detector only the C-band emission. The signal was detected by a Anritsu MS9710B optical spectrum analyzer (OSA). The laser current was kept constant at 300 mA for all the measurements.

III. RESULTS

The thickness of the waveguide was determined using m-line measurements to be 1.25 μm. The refractive index of the films was found to be 1.616 at 633 nm and 1.625 at 453 nm. Since the microsphere and the waveguide were coated using the same sol and the same protocol, and since this protocol was found to be reproducible in previous experiments, we conclude that the thickness and the refractive index of the microsphere coating should be

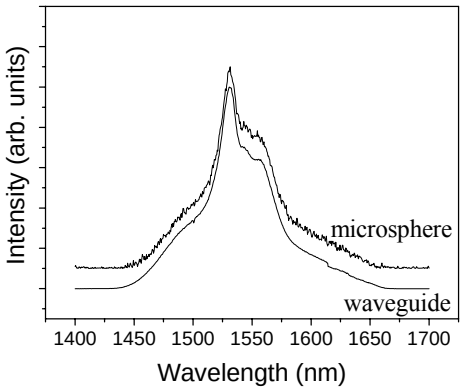

Figure 3. The far-field luminescence spectra of the microsphere and the waveguide upon excitation at 514.5 nm. The spectra are offset for clarity

equal to the ones measured on the waveguide. In Figure 3 are shown the luminescence spectra of the $^4I_{13/2}$->$^4I_{15/2}$ transition of Er^{3+} ions in the waveguide and the microsphere. It can be seen that there is no visible difference in the spectroscopic properties of the waveguide and the microsphere, meaning that the coating procedure is able to deposit the same type of film on both the waveguide and the microsphere.

A low surface roughness is a very important requirement for the microspheres to retain their high Q-factors. Therefore we made AFM (atomic force microscopy) measurements of the surface of the microspheres in order to estimate the effect of the coating on the microsphere surface roughness. Since the microsphere is round, the AFM measurements will in addition to the surface roughness detect also the curvature of the microsphere. To compensate for this the curvature of the microsphere was approximated as a 4th order polynomial and subtracted from the AFM measurements. In Figure 4 is shown a typical AFM profile of the coated microsphere. It can be seen is that in addition to the nanometric surface roughness there is also a number of larger defects present on the surface with heights of about 20 nm. These defects are probably due to the

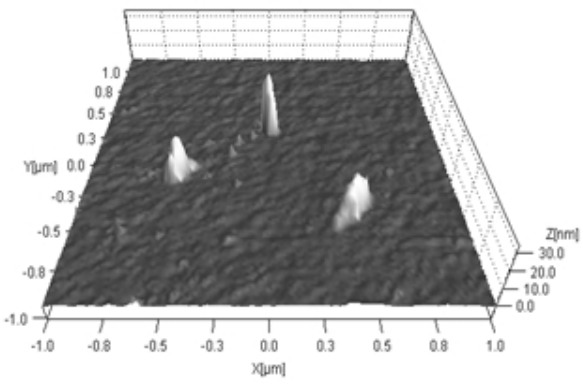

Figure 4. AFM measurements of the coated microsphere

contamination of the surface with impurities in the coating process. To quantify the surface quality before and after the coating two quantities were measured. First, a area of the size of about 1μm x 1μm was chosen where no larger defects were present and the RMS (root-mean square) surface roughness was measured, and secondly a larger area of about 10x7 μm for the coated and 20 x 20 μm for the uncoated microsphere was chosen and the number of macroscopic defects inside this area counted. The results show that the RMS surface roughness is very low for both the uncoated and the coated microsphere, increasing upon the coating from 0.25 nm for the uncoated (bare silica) microsphere to 0.5 nm for the coated microsphere. On the other hand, the density of larger defects was found to increase greatly upon coating from 0.02 defects/μm^2 for the uncoated microsphere to 6.2 defects/μm^2 for the coated microsphere.

The fiber taper microsphere coupling setup was used to detect the whispery gallery modes of the microspheres. A typical WGM spectra is shown in Figure 5. Sharp modes in the region 1540-1565 nm are observed attributed to the WGMs. Actually, the spectrum presented in Figure 5 is only one spectrum measured for a particular coupling point between the microsphere and the taper. In reality the number of modes excited and their intensities depend on the coupling point and on the coupling strength which is determined primarily by the distance of the microsphere to the taper. The spectrum shown in Figure 5 shows 4 modes, but most of the spectra we made show only one or two modes in total. By moving the taper to and from the sphere it is possible to excite different modes. In total we observed five modes centered at about 1543.6, 1550.8, 1554.4, 1558.3 and 1561.8 nm. This modes form a equidistance sequence with a FSR (free spectral range) of about 3.7±0.2 nm. Since the FSR of the WGMs is given by

$$FSR=\lambda^2/\pi Nd \qquad (1)$$

where λ is the wavelength of the mode, N is the refractive index of the sphere and d is the diameter of the sphere.

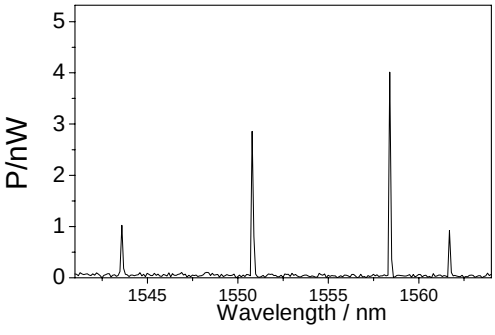

Figure 5. The whispering gallery modes of the coated microsphere.

Since the electric field of the WGMs is greatest near the surface of the microsphere and is hence mostly localized in the coating we conclude that the refractive index to be used in equation (1) should be the refractive index of the coating as measured by m-line. By using the measured values of N=1.63 and d=140±10 μm using equation (1) we get that at 1560 nm the calculated FSR of the WGMs is 3.4±0.2 nm which is in agreement with the measured value. This confirms the attribution of the observed modes as the WGMs. We are not able to measure the Q-factor of the coated microsphere since the measured width of the modes is actually the resolution of our optical spectrum analyzer, but we can conclude that it is greater than the maximum Q-factor we can measure which is $3x10^4$.

The fact that we observe only a couple of modes per spectrum can be explained in the following manner. If the measured spectra were just the spontaneous emission of Er^{3+}, we would have to always detect all the modes with comparable intensity, since the intensity of the modes should increase linearly with the pump power. However, if the measured spectra were the lasing spectrum of the modes we would detect only the modes for which the pump power exceeds their lasing threshold. Since the coupling of the pump power into different modes depends on the coupling point, by moving the taper in respect to the microsphere we can achieve that only some modes are excited. Furthermore, the intensities of the modes would depend exponentially on the pump power and therefore we would have great variations of the mode intensity in respect of the coupling point. In fact for a given mode we observed a wide range of intensity when changing the coupling point, from 1 nW up to 30 nW. All of this is an indication that the measured spectrum presented in Figure 5 is actually the lasing spectrum of the coated microspheres. However to be sure that the observed spectrum is really lasing we would have to make the measurements where we measure the intensity of a single isolated mode in respect to the pump power. However to do this we would have to stabilize the taper and the microsphere mechanically for a time long enough to make the measurements so that the no vibrations interfere with the measurements, and this is not a simple task form an experimental point of view.

IV. CONCLUSION

We have presented the procedure for the coating of silica microspheres using a sol-gel dip-coating technique. We coated the microspheres with optically activated silica-hafnia thin films and characterized them in respect to their spectroscopic and surface properties. We measured the surface roughness of the coated microsphere and found that the coating procedure is able to deposit very high surface quality films. The WGMs of the microspheres were detected in the C-band wavelength range and were attributed to the erbium emission. The overall behavior of the modes when varying the coupling point between the taper and the sphere seem to indicate

that the modes correspond to lasing emission, however to ascertain this hypothesis further measurements need to be made.

ACKNOWLEDGMENT

This research was performed in the framework of the NSBMO research project "Novel silicon based materials for optoelectronics" (2010-2013) of the Provincia Autonoma di Trento and the CNES R&T project SHYRO (2011-2014).

Synthesis Flow for Designing a High Performance Microprocessor

Branimir Malnar
Intel GmbH, Braunschweig, Germany
branimir.malnar@intel.com

Abstract - This paper describes the methodology for the automated synthesis flow used for a high-performance microprocessor project at Intel. The flow presents a standard method of automatically translating the RTL description of the microprocessor to placed and routed gates. The flow optimizes the design for timing and power, while ensuring that the final netlist is logically equivalent to the RTL and that all of the backend checks and rules are satisfied (for example noise, many electrical rules, routing rules, metal reliability, and so forth). The typical inputs to the flow are RTL, timing constraints and floorplan description, while the typical outputs are a netlist and layout. The netlist and layout are used as inputs to the other tools for logical and physical verification of the design.

I. INTRODUCTION

With the advances in the silicon manufacturing technology, the number of transistors that can be placed on a single chip increases dramatically over time. This trend is best described with Moore's law, which states that the number of transistors on a single chip roughly doubles every two years [1]. Naturally, this leads to a dramatic increase in the complexity of the chips, because logic designers can incorporate more features onto a single silicon die. However, the time available for the designers to bring the chip from a concept to a qualified product does not change much with the increased complexity, as the chip development companies try to stay competitive and "do more with less" (effectively reducing the number of engineer-hours in the development cycle, by reducing both the number of engineers and the time allocated for a project).

In the older days when the chips and circuits were less complex, the circuit design was manual in nature, and schematics for circuits were drawn by hand. If the RTL changed, the schematic needed to be manually updated to maintain formal equivalence between the netlist and the RTL. The layout was also done manually by mask designers, and any change in the schematic had to also be manually reflected in the layout.

With the design complexity in microchips today, this method of circuit design would not work if applied onto the entire chip, because it would require too many engineer-hours to be feasible. Therefore, the CAD tools that automate circuit design are becoming more and more important and today are widely used [2]. A general term to describe the automated method of generating circuits is synthesis. Synthesis did not replace the manual effort of engineers completely, but it is significantly reducing the chip design effort. Generally speaking, synthesis tends to produce lower quality circuits (in terms of the power consumption and the maximum frequency on which the circuit can operate) compared to the manual effort of an experienced circuit designer – although with the advances in synthesis tools this gap is shrinking with time.

In general, the physical design methodology for digital circuits on our project can be divided into three major design styles [3]:

- Structured datapath flow (SDP) for timing critical portions of the design, for which the designers want complete control over the circuits. SDP methodology assumes that the designer draws the schematic by hand and instructs a CAD tool on how the cells should be placed in the layout. The cells are then routed using an automated tool (sometimes the manual preroutes are done beforehand for the critical wires). The designer has a large degree of control over the final schematic, the cell placement and the routes.
- RTL-to-Layout Synthesis flow (RLS) for large portions of logic that is less timing critical. The schematic, placement and routing of cells is completely automated, and the schematic and layout are generated by the synthesis tools from the RTL, based on timing constraints and the area available for the given portion of the chip. The control over the schematic and placement is relatively low compared to the SDP style, but as long as speed and power requirements of the circuit are satisfied, the details do not matter.
- Register files automation flow (RFA) for the design of the register files, i.e. structured arrays of registers used on the chip for wide range of purposes. The goal of this flow is to automate the creation of these highly structured arrays as much as possible, to cover many different types such as RAM, CAM, with multiple read and write ports, with and without decoders, etc. The task of creating all register files for the chip typically falls on one central team, and the RFA flow as such is typically not used by many designers on the project.

In this paper, the RLS flow components will be described with more details, while the SDP and the RFA flows fall outside of the scope.

II. DESIGN PARTITIONING

One of the most critical tasks, which is done early in the project, is partitioning of the chip into smaller building blocks [3, 4]. Depending on the complexity of the chip and the die size, there could be multiple levels of hierarchy below the full-chip level (FC). Without losing generality, we can assume three levels, namely the full-chip level, the section level and the block level, as shown in Figure 1. The main reason behind the partitioning of the design is the divide-and-conquer approach to the design – it would be impossible or inefficient to design the whole chip as one block.

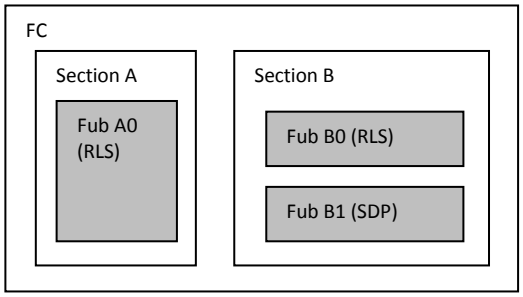

Figure 1. Hierarchy levels in chip design

The sections are typically defined such that each section comprises certain functionality. For example, in a microprocessor design there are sections for interconnect between the cores, the controller for the off-chip memory, DDR protocol, PCI protocol etc. Each section can be developed relatively independently from others, and each has a dedicated team of experts working on it. The global team, which works at the FC level, is responsible for integration of each section into the full chip.

The lowest level of hierarchy is often called a fub (the acronym stands for Functional Unit Block). The fub is typically what is being created in terms of netlist and layout generation. For example, a fub would be something that a designer would run the RLS flow on. The RLS flow is never run at the section or the FC level, and the same is true for the SDP and the RFS flows. The sections are made of fubs by using the bottom-up approach, and the full chip is made of sections in a similar way. For example, to get the section netlist, the netlists of the fubs belonging to that section are stitched together by a full-chip netlister tool. Similarly, the layout of each fub is rolled up into the full-chip layout tool, where the entire sections and eventually the whole chip are assembled.

III. OVERVIEW OF THE RLS FLOW

The high level overview of the RLS flow steps is given with the diagram in Figure 2 [5]. As already stated, the RLS flow is run at the fub level, and the main inputs are the fub RTL, timing constraints and floorplan data.

A. RTL

The RTL represents the logical description of the fub, and the goal of the RLS flow is to translate that RTL to standard cells, while maintaining functional equivalence between the RTL and the netlist [2]. It is important to note that RLS uses a library of cells for implementation of the RTL functionality. In other words, RLS is Cell Based Design (CBD). Detailed analysis of the library requirements falls outside the scope of this text, but in general the library contains flops, latches, buffers, inverters, and combinatorial logic cells (such as NAND, NOR, XOR, OR-AND-Invert, AND-OR-Invert , and so forth). There are also technology dependent physical-only cells used for various DFM purposes, spare cells for ECO etc. They are not part of logic synthesis, but are inserted at various points in the physical synthesis flow.

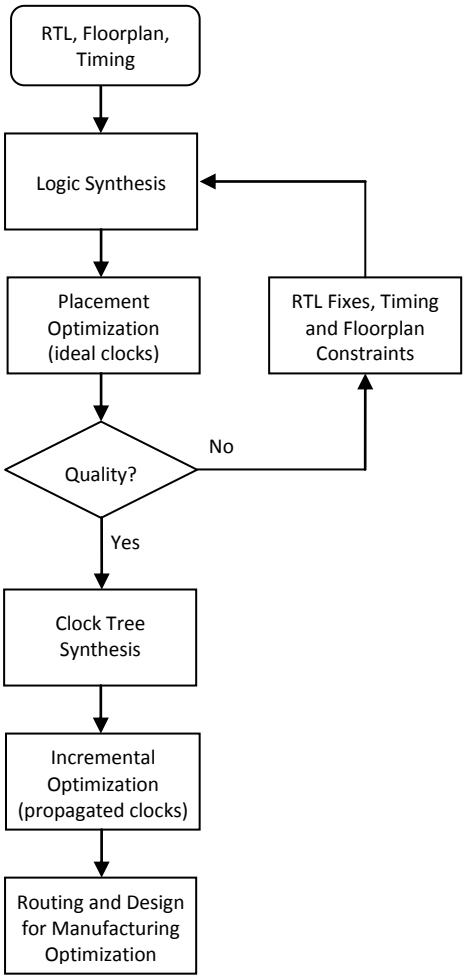

Figure 2. RLS flow steps

The functional equivalence between the RTL and the final netlist coming out of the RLS flow is checked by formal equivalence tools, but that is not the part of the RLS flow. It should be noted that the state of the art synthesis tools used today are sophisticated enough to generate netlists without functional bugs (almost always), so the designs coming out of synthesis are correct-by-construction from the logic point of view.

B. Timing Constraints

The fub timing constraints are generated at the section level, and rolled down to fubs. The timing constraints have all the information that RLS needs to optimize the logic correctly for timing [6]. There are several main categories into which they may be divided:

- All the clocks for a fub need to be defined in the constraints. Typically, the constraints rolled down from the section only contain the clocks that are driven to the fub from the section. However, there are sometimes also clocks generated internally inside the fub, and those are either defined by the user, or special RTL macros are used to generate them automatically when the RTL is read during logic synthesis.
- The input and output constraints specify timing requirements at the fub interface. They essentially describe how much time the signals that cross the fub boundary are allowed to spend inside the fub. Apart from the timing information, the input ports are further described by the transition time of the input signals and by the maximum capacitance that the synthesis tool is allowed to connect to the input port inside the fub (internal wire capacitance and the capacitance of all pins connected to the wire). On the other hand, the output ports are also described with the external capacitance connected to the output and the required transition time, so that the synthesis tool can properly size its driver.
- By default, the signals are timed from the launching to the capturing edge of the clock, and the delay of all the elements in the path between the registers needs to be less than one clock cycle. However, there are signals which are allowed to take more than one cycle, and this information can be provided via so-called multi-cycle overrides (MCO). These MCOs are typically specified on the driver of the signal. If they cross the fub boundary, they will also appear at the section level, and be rolled down to all of the receiving fubs. If the MCOs are contained entirely inside a fub, they will not appear at the section level. It is important to note that MCOs are potentially dangerous, because if applied incorrectly, they can cause circuits to not operate at the desired frequency. These so-called "silicon escapes" are very costly, and therefore it is crucial that all MCOs are properly reviewed – and often.

Once the fubs are synthesized and they roll their timing information up to the section level, the timing paths between the fubs also have to be checked. This is done by representing fubs as boxes which only have their interface modeled (timing paths internal to the fubs are not checked at the section level). The timing tool calculates the slack on each section path; that slack can be positive if the path is meeting the timing requirements and negative if it is not. The slack is distributed to the driving and the receiving fubs by means of adjusting the timing constraints for each given fub. The timing requirements are also checked above the section level, i.e. at all the levels of hierarchy, including the full chip level [7]. To satisfy the tapeout requirements, all timing paths at all the hierarchy levels must have positive margin.

C. Floorplan

The floorplan data primarily define the bounding box for the fub where all the standard cells implementing the fub RTL need to be placed, and the locations of input and output ports of the fub. Additionally the floorplan data contains the pre-routes that go over the fub (and thus take away the routing resources of the fub), routing keepout regions, placement keepout regions, the power grid and the clock grid. The floorplan data for fubs come from the full chip layout tool, which is the primary tool for full chip integration. Initially at the beginning of the project, the full chip layout tool is populated with the section and fub data, i.e. the size of all the sections are defined, and they are placed in the full chip floorplan and divided into fubs. As the RTL is coded, the fubs interfaces are continuously changing and the section layout owner maintains the port placement and the routes between the fubs and the sections. It is very important that the new ports in the RTL get placed in the floorplan as soon as possible, because the synthesis tool places unplaced ports to some random locations away from the optimum locations, causing timing issues at the fub and the section level. It is important to note that port placement for fubs is defined together between the fub owner and the section owner, because they have to find an optimum location for the fub internal timing, but also with respect to placement of other fubs in the floorplan.

Floorplanning is one of the most critical tasks in the microprocessor design [8]. Most of the floorplanning work is done early in the design phase, because the placement of sections and fubs need to be defined early to drive the convergence work and the global critical paths between sections need to be understood and analyzed for timing. It is also crucial to ensure that the global buses can be routed with given routing resources. Late changes in the floorplan can be very costly, and need to be avoided by quality planning upfront.

From the fub design perspective, floorplanning needs to ensure sufficient area and good aspect ratio for all fubs. At the fub level, the fub designer needs to optimize the port placement in a way that meets section requirements and also drives convergence of fub internal timing. If the fub also contains memory blocks as embedded black boxes, their locations also need to be optimized to ensure timing convergence and to avoid routing hot spots in the fub. Figure 3 shows an example of a fub floorplan. The boundary of the fub is not rectangular, but rectilinear. All of the macros are pre-placed in the floorplan by the

designer, and the standard cells are not shown because they are unplaced at this point. Once the floorplan is verified not to have shorts and illegal overlaps, it is ready to go the next step, which is standard cells placement optimization.

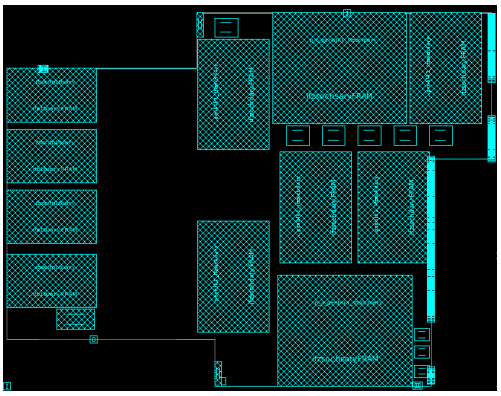

Figure 3. Floorplan example

It is important to note that poor or incomplete floorplans generate bad and unrealistic results in the RLS flow (the principle of garbage-in-garbage-out always holds true in RLS). On the other hand, RLS is often used early in the RTL development to validate the architecture and the early logic design from the timing perspective. The quality of the RTL is therefore difficult to measure with RLS in the early stages due to the lack of good floorplan, and that is yet another reason to drive the quality floorplanning work early in the design phase.

IV. LOGIC SYNTHESIS

There are several commercial tools available for logic synthesis. The one widely used at Intel is Design Compiler (DC) by Synopsys, one of the largest providers of EDA tools [9]. The primary goal of logic synthesis is transferring the RTL description of the fub to the gate level netlist, which is optimized for power and timing. The main inputs to DC, together with the RTL, are timing and floorplan constraints, and the main output is the design database that contains the netlist and some other important design attributes. This database serves as the input to the place and route tool, which optimizes it further.

DC is a very powerful tool for logic synthesis and optimization and it can concurrently optimize for timing, power and area by invoking complex algorithms for logic optimization and by exploring possible datapath solutions from the library of existing components [9]. In addition to logic optimizations, we use two other Synopsys tools that run under inside DC (but require special licenses to be invoked), namely Power Compiler [10] and DFT Compiler [11]. Some of these features are described in the following text.

A. DesignWare Library

DesignWare (DW) is a library of predefined components and solutions available in DC for implementation of complex digital circuits. This library is probably the largest single library of IP available today. In synthesis of microprocessor blocks, we are mostly using only a small, but nevertheless a crucial portion of it, namely datapath components.

Using the DW library requires a special license, but today in the modern design of complex digital circuits it is almost a must to use it. In general, the quality of results with and without DW is immense. DC is very efficient in using a wide selection of predefined multipliers, adders, DSP components etc., and exploring several solutions to choose the most optimal one for the given application. Without DW, DC uses logic synthesis algorithms for very complex designs and manages to implement them, but with a significantly lower quality of results.

Apart from the datapath components, DW contains a wide range of IP that ranges all the way to complete microcontroller cores, USB, PCI, DDR, and many more. It is important to note that all of these components are available in a technology independent form, and then mapped to the standard library and optimized by DC.

B. Power Compiler

Power Compiler (PwC) is a tool that optimizes the fub for power. It runs concurrently with the rest of optimizations in DC, and it is used for leakage and dynamic power optimization. Running PwC under DC is optional and it requires a special license.

PwC has the capability to take into account activity factor for signals to model dynamic power with greater accuracy. These factors can either come from the simulation environment, or default values can be provided. If several simulation tests are provided in terms of the signal switching activity, DC can read all of them and optimize the netlist concurrently for all of the tests. More important tests (the ones that occur more frequently in real life) can be modeled with greater weight.

PwC can also be used for clock gating insertion, but this feature is not always used. In high frequency designs, such as microprocessors, clock networks are critical design blocks, and need to be well controlled. That is why in those cases clock gating is mostly coded in the RTL and automated clock gating in synthesis is not allowed.

For any power optimization to generate good results, the standard cells library needs to be well characterized for power, which is often a challenge.

C. DFT Compiler

DFT Compiler is used for scan insertion. It is important to insert scan as early as possible in the RLS flow, so that DC would also see the area impact of scan flops and routing congestion impact from all of the nets related to scan. This is important, because it improves correlation between logic and physical synthesis, and therefore the quality of the results. The method from the past to perform logic synthesis

without scan and physical synthesis with scan has proved to be suboptimal. It was the method of choice simply because of lack of tools able to support scan insertion concurrently with logic synthesis.

After logic synthesis the fub is represented with the netlist, but it still has to be placed and routed. This is done in the next steps with the place and route flow. Although some optimizations for timing and power are still performed after logic synthesis, it is important to note that the capabilities of the place and route tools are limited with respect to that. Therefore, logic synthesis presents the first crucial step to make sure that the design quality in terms of timing and power is met.

V. PHYSICAL SYNTHESIS

Physical synthesis is an expression used for all steps of the RLS design after logic synthesis, i.e. after mapping RTL to standard cells (which also includes gate level optimizations for timing, power and area, as mentioned earlier). There are several commercial tools available for physical synthesis, and the one mostly used at Intel is IC Compiler (ICC) by Synopsys [12]. ICC has many built-in capabilities, including placement optimization, clock tree synthesis, routing, DFM related optimizations, signal integrity and multi-corner optimizations, multi-voltage design, and pretty much anything that is needed in the backend design of modern chips. However, not all of the capabilities are used in the design of modern microprocessors, for several reasons.

One reason is that microprocessor projects take much longer compared to some other simpler chips. For that reason, microprocessors are not adopting the newest DC and ICC versions immediately upon their release, because it takes some time to test the existing RLS flow with the new tool versions, and to fully adopt them. Updating the tool versions in the RLS flow is not a straightforward task, and may cause instability in the flow and lead to a loss of quality of results. This is because the flow might be well tuned to a certain version of ICC, but not to others, since optimization algorithms evolve and change with every release. And since the RLS flow does not necessarily adopt the new tool versions quickly as they become available, they are also not adopting the newest features available in them.

Another reason why not all ICC features are used in the microprocessor design is because they are simply not needed. For example, in terms of the floorplan size and the number of cell instances, the RLS fubs in microprocessor projects are much smaller on average compared to the RLS fubs in SoC designs [2, 8]. There are several reasons for this, but they fall out of the scope of this text. Partitioning of the fubs in the microprocessor design is simply done in the way that there are typically no fubs that span multiple voltage domains. Hence, in our flow we do not support multiple voltage design, since it is simply not needed.

The following text describes the major steps in our physical synthesis, as depicted on Figure 1.

A. Placement Optimization

ICC takes as an input the DC database with the synthesized and optimized fub netlist, and the same floorplan and timing constraints that were used by DC. It places the cells in the floorplan and further optimizes the netlist to make sure that the timing, power and area goals are still met, and that the placement of cells is suitable for routing, i.e. that there are no routing hot spots in the fub. ICC uses smart placement optimization algorithms and takes into account placement and routing blockages and preroutes from the section. Since the nets are not fully routed during placement optimization, ICC estimates them by using the built-in virtual router and tries to correlate these estimated routes with the final routes to avoid problems during routing. The output of ICC is the database with the netlist that is further optimized for timing, power and area and in which all of the cells are placed at the legal locations in the floorplan.

It is important to note that all of the optimizations done so far, both in DC and ICC, are using clocks as ideal networks. In other words, the RLS flow sets ideal clock latencies on all of the elements in the clock networks up to the clock pins of the registers. These latencies are carefully specified to be as close as possible to the propagated clock delays after CTS, so that static timing analysis of all paths before and after CTS (i.e. with ideal and with propagated clock delays) correlates well. One of the most important aspects of CTS is to make sure that these latencies match as close as possible [13]. Typically the target is set to 10% of ideal versus propagated delay on all of the receiving clock pins in the clock network.

B. Clock Tree Synthesis

Clock tree synthesis (CTS) is performed after the design is fully placed, because at this stage the placement of all of the clock receivers (such as flops, latches and hard macros) is known. There are two different types of CTS flows used: fast clock CTS and slow clock CTS.

Fast clock CTS is used for the clocks with relatively high frequencies. These clocks are distributed via the global clock network to individual fubs, where they are represented as a grid of clock spines in the floorplan [14]. The fast clocks are coded in the RTL to typically have a buffer tree of two stages between the grid and the clock receivers, and this depth needs to be preserved after CTS. In other words, fast clock CTS does not insert additional buffers to the clock tree, but simply duplicates the existing buffers and connects them between the clock spines and the receiving flops and latches. The duplication algorithm is coded entirely in TCL and does not use built in capabilities of ICC. The hard macros are typically connected directly to the clock grid, since their clock distribution is entirely implemented inside the macros.

Slow clock CTS is used for the clocks with relatively low frequencies that have a single point of entry in the fub, i.e. one input port. From that input, a tree of buffers is built to all of the clock receivers by a built-in CTS function in ICC [12]. The buffer tree depth can vary from one run to another, since the number and the placement of clock receivers also vary due to the changes in the RTL. However, that variability is not a big issue because the timing paths associated with these clocks typically have significant positive margins due to a relatively high cycle time.

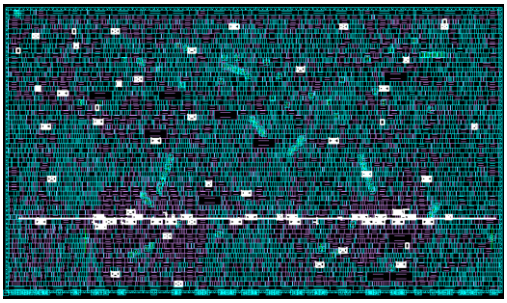

Figure 4. Fast clock tree

Figure 4 shows an example of the fast clock tree. The clock spine running horizontally across the floorplan of the fub is shown as a straight white line. Typically for bigger fubs, there are several clock spines running in parallel to one another, but in this case the fub is relatively small, and therefore has only one spine. The cells in the first stage of the clock tree are placed underneath the spine, to minimize the wire length and reduce the load on the global clock drivers outside of the fub. These cells can be seen in Figure 4 as white boxes grouped around the spine. The cells in the second stage of the clock tree are scattered around the fub. They are driven by the first stage cells, and they are driving the clock to the registers. The registers are not shown, but they are also scattered around the floorplan, as decided by the placement algorithm of the placer.

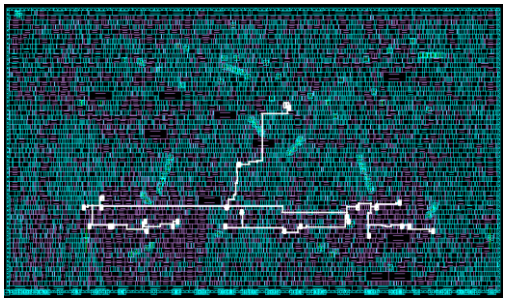

Figure 5. Slow clock tree

Figure 5 shows the slow clock tree of a test clock in the same fub as shown in Figure 4. Only a few stages of the tree are shown. The source of the clock is a single port placed near the middle of the floorplan. From that point, the tree of buffers is driving the clock to the registers, which are scattered around the floorplan.

As already stated, before CTS the clock tree does not exist and the loading on clock ports and clock drivers is too large, so the entire network is treated as ideal. After CTS, the ideal setting is removed and the clock propagation is timed by the timing engine. During CTS each clock cell is sized properly to meet transition time, max capacitance and other ERC requirements. The clock related ERC requirements are typically tighter than those for regular signals, and the CTS flow is tuned to meet all of these requirements concurrently. To achieve that, not only are the built-in ICC commands used in CTS, but also a significant portion of the flow is custom developed in the TCL scripting language, especially around duplication and clustering of cells in the fast clock trees and sizing of clock cells in both the fast and the slow clock trees.

As a part of CTS the fast clocks are also routed, because they have tightest requirements in terms of electrical rules (for example transition times and shielding), so they are given priority in terms of routing resources utilization [15]. In the process, these routes are frozen, and the subsequent optimizations steps are allowed to modify them only with minor changes for DRC related reasons (this ensures that their metal usage does not change significantly). The slow clock nets are routed together with the signal routes later in the flow, since they have similar ERC requirements.

C. Incremental Optimization with Propagated Clocks

As already stated, the clocks are treated as ideal before CTS and as propagated after CTS. Therefore, the clock network timing look different pre- and post-CTS. In the fast clock tree, the goal of CTS sizing is to match ideal and propagated clock delays for each clock receiver as much as possible (within 10%), but there are always certain differences between the two, since the tools are not perfect. In the slow clock tree, the tool inserted several stages of buffers, so the clock delay after CTS differs even more than in the fast clock trees. Because of all these differences, another set of timing optimizations needs to be performed to make sure that all paths still meet timing. This is done via incremental optimizations in ICC, which include cell sizing, buffering and simple logic optimizations and placement refinement.

It is important to note that all of the elements in the clock trees are fixed at this point, and they cannot be modified during this optimization step. This is due to the fact that the clock trees are fully optimized and cannot change.

Typically, the optimization in this step is done in two stages. In the first stage, the paths are optimized for hold time violations, and in the second stage they are optimized further for setup time violations. Before these optimizations, all of the signals are routed with a quick routing process that assigns the routes to layers, but does not work on DRC violations. This ensures that the optimizations are done with the routes that correlate well with the final routes, but

also that not too much time is spent fixing the DRC violations.

D. Routing and Post-Routing Optimizations

After CTS is completed and design is further optimized for timing with propagated clocks, all nets are ready to be routed. The routing rules are described in the technology file, which is one of the most important configuration files for ICC, where all routing rules are defined [16]. ICC has two available routers, a so-called classical router and a new Z-router, which is the next generation router with an improved engine. The latter is used at Intel at least in the major microprocessor projects in the most advanced process nodes. The goal of the routing process is to get a fully routed design with zero design rule violations [17]. However, since the routing process is not perfect, there are typically some violations that remain for manual cleanup. The quality of layout is considered good with about 10 violations for 30 thousand standard cells (most of the fubs easily achieve that).

Once the design is routed, all the nets are fully connected and we see the DRC optimized wires for the first time in the flow. Up to this point, the wires were estimated to a certain degree. Depending on how good the correlation is between the estimated and the real routes, the timing picture will change to a certain degree after routing. The goal of automation is for this change to be very small and manageable.

Since the pre- and post-layout timing correlation is not perfect, additional optimization is performed post routing, to recover the lost timing margin. This optimization is often performed with preserving the cell footprint, so that the routes do not need to be repaired. Blocks with critical timing paths are also allowed to turn on usage of cells with low threshold voltage at this stage, to clean up the remaining timing violations. Normally, these cells are disabled to save leakage power (most of the fubs can meet timing by using only high threshold voltage cells).

E. DFM Optimizations

At the end the RLS flow needs to take care of certain DFM rules to satisfy layout quality requirements from the manufacturing perspective. These requirements are checked in the sign-off tools that perform backend checks, and the RLS flow needs to make sure that the RLS fubs have layout that passes these checks. The rules and requirements are dependent on the process technology, so they can differ from one process node to another. However, the typical requirements are always the same: the metal fill is inserted to meet the density requirements, filler cells are inserted in the empty areas of the floorplan, antenna violations are resolved, etc. In addition to that, the spare cells are added to the design to facilitate manual ECO fixes in the post-silicon debug [17].

DFM insertion can add significant perturbations to the design that potentially require additional optimization steps to resolve new timing and ERC violations. However, if the DFM components such as fill are emulated in the pre-DFM portion of the flow, these steps can be unnecessary, because their impact is already modeled and accounted for. Exactly for this reason, in our flow the post-DFM optimization steps were not necessary at all.

At the end of the DFM portion of the flow, the RLS fub is ready for sign-off checks to make sure that all of the requirements are met. The main outputs from the RLS flow are the layout and the netlist, together with some other files that are specific for each individual sign-off tool (e.g. a map file for formal verification and so forth).

VI. SIGN-OFF TOOLS

At the end of the RLS flow, the fub is ready to go through sign-off checks to ensure that a certain desired quality for the project milestone is met (this is true for early milestones as well as tapeout at the end of the project). The RLS flow is a creation tool, not a sign-off tool. In other words, it creates fubs, and everything it does must be checked for quality with other tools [18].

The number of tools and the quality requirements depend on the project milestone. Some tools, like sign-off timing and formal verification, are required for all of the milestones, albeit with different requirements (for example, the fub does not need to be timing clean for early milestones). On the other hand, RV and IR drop for example are seldom run before the second half of the project, partially also to allow the teams to concentrate on the RTL development and early timing and power convergence. Such decisions and general requirement are made by the project management and the design automation groups.

VII. CONCLUSION

This text shows the high level overview of the RLS flow for a high end microprocessor design at Intel. All of the steps are described and the methodology presented with a certain level of details. They show that the RLS flow for a microprocessor follows a standard methodology of synthesizing digital circuits, but certain methodology decisions are specific for high performance designs. Great emphasis is given to timing convergence, which is obvious in fast clock synthesis methodology, relatively small fub size, and careful tuning of the flow for pre- and post-layout correlation.

Abstract - Porous silicon (PSI) samples were prepared by electrochemical etching of n-type (111) epitaxialy grown silicon layer on n-type silicon (111) substrates, by varying the concentration of 48% HF in ethanol solution, and by varying the etching time. Electrical resistivity of epitaxial layer was ~2 Ω cm and of silicon substrate was ~ 0.015 Ω cm. Within the epitaxial layer, and on the substrate surface, the micro- and nano-pores of different sizes in dependence on HF concentration and etching time were obtained. With the etching time longer than 30 minutes, the epitaxially layer was detached from the substrate. The structural and optical properties of prepared samples were investigated by Raman and photoluminescence spectroscopy, field emission scanning electron microscopy (FE-SEM) and energy dispersive x-ray spectroscopy (EDS) spectroscopy. The FE-SEM images showed high density of micrometer sized pores on epitaxial layers. After detaching the epitaxial layer, the substrate showed fine nanometer sized cobweb-like silicon structures whose morphology and density depend on HF concentration and etching time. The Raman spectra of such structures show transversal optical (TO) phonon band that broadens and red-shifts depending on the size of silicon nanostructures. The size distributions of the silicon basic structural units where determined by applying the phonon confinement model and were compared with those determined by FE-SEM. The intensity of phtoluminescence peak of such fine porous substrate shows the sensitivity on a degree of optical phonon confinement.

I. INTRODUCTION

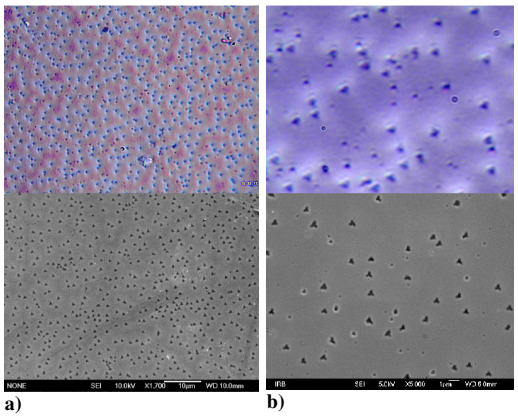
Porous silicon (PSi) was established as a promising optoelectronic material since Canham's discovery of intense PSi photoluminescence at room temperature in the visible light spectrum in 1990 [1]. However, bulk silicon exhibits up to five orders of magnitude weaker photoluminescence than PSi as a material with indirect energy band-gap [2]. Several models have been successful in describing photoluminescence in Psi. The most promising candidates were quantum confinement models [3], but some evidence suggests that luminescence properties of PSi may not simply be due to quantum confinement, but also due to surface chemistry effects [4]. A large amount of work demonstrates that the surface of freshly prepared PSi is hydrogen passivated. However, exposure of the porous silicon to ambient air for prolonged period leads to the slow oxidation of PSi films [5–8]. It is now well established that electropolishing of silicon begins for the current density $j > j_{crit}$ [9]. Anodization of n-type c-Si in concentrated HF solution leads to the fabrication of the microporous silicon. In the present work the studies of structures and composition of porous silicon prepared on epitaxial layer grown on silicon substrate were carried out in detail depending on HF concentration in the electrochemical solution. Silicon can be electrochemically etched in hydrofluroric acid (HF) solutions and at specific current densities, local dissolution of silicon atoms occurs, such that low density porous crystalline silicon is formed. Here we show the results of preparation of porous silicon samples from n-type silicon epitaxial layer grown on more conductive n-type silicon substrate. By varying the concentration of 48% HF in ethanol solution micro- and nano-pores of different sizes within the epitaxial layer in dependence on HF concentration were obtained.

II. EXPERIMENTAL

A specially designed electrochemical etching cell was used for preparation of PSi samples from commercially available silicon-on-insulator wafers, consisting of 20-24 μm thick n-type (phosphorus doped) silicon epitaxial (111) layer grown on a 280 μm thick n-type (Sb doped) silicon substrate. Electrical resistivity of the epitaxial layer is about $\rho_1 \approx 2$ Ωcm. Silicon substrate is a much better conductor with resistivity of about $\rho_2 \approx 0.015$ Ωcm. The bottom of the wafers was coated with gold for electrical contact with the bottom part of the etching cell. Three samples were prepared by varying the concentration of 48% HF in 96% ethanol solution in the electrochemical etching cell. Concentrations of 25%, and 50% of 48% HF in 96% ethanol solution were used at constant current density of 13 mA/cm^2 provided for 30 minutes for the samples S1 and S2, respectively and the concentrations of 50% of 48% HF in 96% ethanol solution for 80 minutes at the current density of 16 mA/cm^2 for the sample S3.

III. RESULTS AND DISCUSSION

FE-SEM and optical microscopy images of the surface of the epitaxial layers of the samples S1 and S2



a) **b)**

Figure 1. Morphology of the top surface of the epitaxial layer of the samples S1 at magnification of 1700 **a)** and S2 at magnification of 5000 times **b)**. Upper images were taken by the optical microscope at the same magnification as that bottom taken by the FE-SEM.

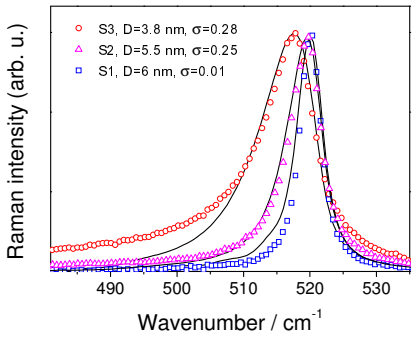


Figure 2. Raman spectra of the samples S1-S3 (symbols). Full line is the fit by Eq.(4) with mean particle diameter D and size distribution width σ as the free parameters.

are shown on Figure 1. The triangle-shaped holes were produced by electrochemical etching. Such types of holes usually appear by etching process on dislocations.

Figure 2 shows the Raman spectra in the spectral range of TO(Γ) vibrational band at 520 cm^{-1} of the substrate layers for our three samples. The broadening and redshift of the c-Si transversal optical TO(Γ) vibrational band at 520 cm^{-1} occurs due to the phonon confinement effects. Fig. 2 shows the results of fit on the optical mode of silicon with mean particle diameter D and size distribution width σ as free parameters. It is interesting that this procedure gives 3-4 times smaller dimension for the correlation length of phonon confinement than as directly measured by FE-SEM This indicates that silicon cobweb-like wires have substructure that are not visible by FE-SEM. To better understand this effect the high resolution TEM images will be performed on the samples in the near future.

IV. CONCLUSION

Porous silicon (PSi) samples were prepared by electrochemical etching of thin epitaxial silicon layers on silicon substrates. Micrometer sized pores in eptaxial silicon layer were caused by electrochemical etching process through the dislocation channels. FE-SEM images of substrates after epitaxial layer detaching showed high density of micrometer sized pores separated by the cobweb-like silicon structures whose morphology and density depended on the HF concentration and etching time. The Raman spectra of such structures show transversal optical (TO) phonon bands that broaden and red-shift depending on the size of silicon nanostructures. The diameter distributions of the cobweb wires where determined by applying the phonon confinement model. When compared to the FE-SEM diameters, they are 3-4 times smaller indicating the existence of silicon substructure not observable by SEM microscopy that exists in formed cobweb-like silicon structure.

Abstract - Luminescent porous silicon (PS) was obtained by galvanostatic electrochemical anodisation of p-type polycrystalline silicon (poly-Si) film in aqueous hydrofluoric acid (HF)/ethanol electrolyte. Poly-Si film was prepared and boron delta-doped on n-type silicon wafers by low pressure chemical vapor deposition (LPCVD) process. Porous poly-Si surface morphology varied as a function of anodisation time. Scanning electron microscope (SEM) images have shown macro-porous Si formation along grain boundaries. S-band photo-luminescence (PL) was measured in all samples, while Raman measurements indicated minimal or no confinement effects.

I. Introduction

Porous silicon is created by partial dissolution of silicon host material, typically by electrochemical anodisation of crystalline silicon in HF containing electrolytes. Porous silicon shows intensive photoluminescence in visible part of the spectrum, which is thougt to be caused by quantum confinement effect in silicon nanocrystals present in PS [1,2].

PS can also be prepared on polycrystalline silicon substrates. Literature search shows that only about 1% of all research papers regarding PS focus on porous poly-Si. However, the use of poly-Si has been expanding due to its lower price than semiconductor-grade monocrystalline silicon. This opens possibilities for industrial applications of porous poly-Si films in cases where their properties are found interesting.

II. Experimental

A. Poly-Si layer preparation

Poly-Si films were deposited on silicon {111} oriented n-type wafers. Wafers were double-layered, consisting of 280 μm thick Sb-doped substrate (ρ=0.015 Ωcm) and epitaxially grown and polished top layer (phosphorus doped, 4.2-5.3 μm thick, ρ=0.8-1.0 Ωcm).

Wafers were solvent cleaned and dipped in 1% HF for three minutes for pre-deposition oxide removal.

Poly-Si was deposited and boron delta doped by LPCVD process. Working gas was 26% SiH_4/Ar. Process was performed at 680ºC at working pressure of 50 Pa. Poly-Si was deposited in two steps of 100 minutes, between which poly-Si was boron delta doped by flushing the reactor with 20 cm^3 of BCl_3 gas. Post deposition samples were annealed for 30 minutes at 1050ºC in nitrogen gas flow at atmospheric pressure.

Deposited poly-Si film thickness was 6,5 μm measured by SEM of a sample cross-section. Sample resistivity was measured by 4-contact probe method, ranging from 3-14 Ωcm, corresponding to positive charge carrier density of $\approx 10^{17}$ cm^{-3} [3].

B. Porous poly-Si preparation

Samples were anodised in a vertical anodisation cell with O-ring. Electrolyte was 5% w/w solution of HF in ethanol prepared from 40% aqueous HF acid. Anodic contact was accomplished with aluminum foil pressed between the sample back side and the cell base. Cathode was a platinum spiral wire inserted in electrolyte. Voltage source was connected to anodisation cell. Current and potential drop on the cell were measured continuously during the anodisation.

PS electropolishing current j_{PS} was measured from I-V curve measurement (6 mA/cm^2 < j_{PS} < 8 mA/cm^2). For sample preparation anodisation current was kept constant at 3,4 mA/cm^2. Anodisation time was varied (3,5,10,15,30 and 75 minutes).

After the anodisation samples were twice rinsed in ethanol and twice in pentane. Final pentane rinse was continued for 5 minutes in order to reduce the capillary stress during sample drying [4]. Samples were left to dry in air.

III. Results and Discussion

A. Poly-Si layer

Prepared poly-Si sample surface consisted of partially fused grains consisting of multiple fused silicon microcrystals. Least-squares Gaussian fit to Feret's diameter of selected sample of grains gives a value of d=(1,1±0,4) μm. Features about 50 nm in diameter were recognizable on grain surfaces.

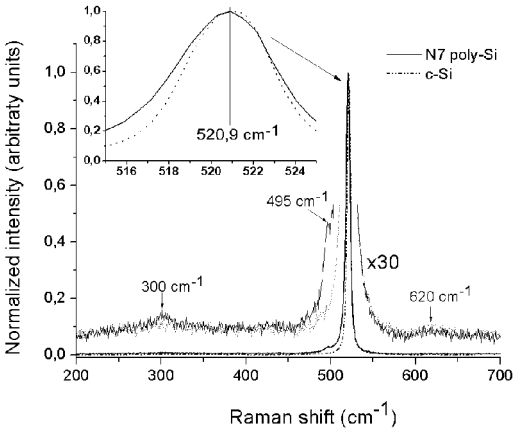

Figure 1: Comparison of Raman spectra of crystalline Si (dashed line) and prepared poly-Si (solid line) samples

Fig. 1 shows Raman spectra of poly-Si sample N7 in comparison with monocrystalline silicon. Spectra were recorded in same conditions and normalized by intensity. Inset shows Raman shift range from 515-525 cm^{-1}. Widening of silicon O(Γ) Raman vibrational band at 520 cm^{-1} in poly-Si is clearly visible. Due to phonon confinement effect, O(Γ) band can change position and shape in silicon nanocrystals. One of phonon confinement models was given in [5]. Raman band widening can also be due to crystal defects which are present abundantly in poly-Si [5].

Peak positions for all samples have shown small shift towards the lower wavenumbers (0,1 – 0,3 cm^{-1}). Such small Raman shifts can be attributed to silicon nanocrystals sized from 20-40 nm in diameter by phonon confinement effect, which is consistent with SEM micrographs. No measurable photoluminescence was observed from bare poly-Si samples.

B. Porous poly-Si

Six samples with anodisation times of 3,5,10,15,30 and 75 minutes were prepared. Other anodisation parameters were kept constant.

Fig. 2 is a SEM micrograph of prepared porous poly-Si sample N7, showing large macropores along the

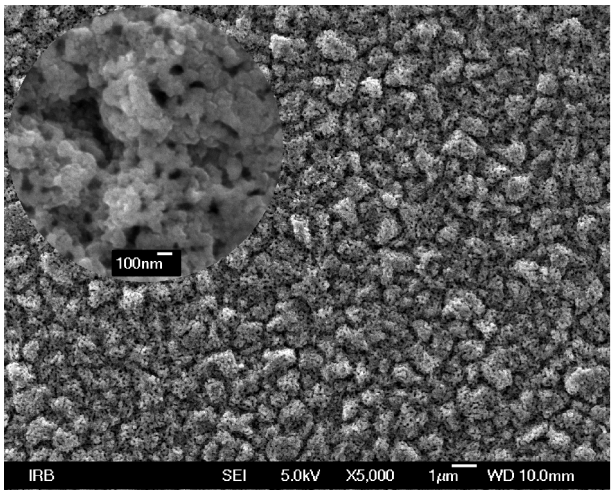

Figure 2: SEM micrograph of sample N7 anodised for 3 minutes, showing typical porous poly-Si surface morphology.

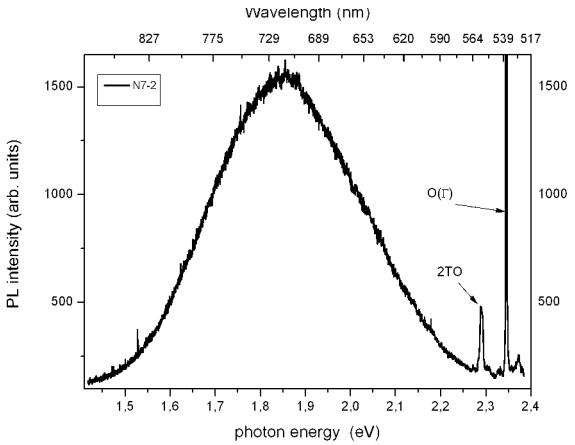

Figure 3: Photoluminescence spectrum of porous poly-Si sample N7

poly-Si grain boundaries and mesopores on the grains themselves.

No Raman O(Γ) band downshifting was observed in comparison to poly-Si substrates. This indicates absence or very low concentration of silicon nanocrystalites. Weak s-band photoluminescence was observed in all porous poly-Si samples.

Photoluminescence spectra were Gaussian, centered at 1,85 eV with FWHM of 0,4 eV (Fig. 3). PS photoluminescence can be attributed to quantum confinement (QC) effect [2]. QC model relates silicon crystalite size to PL peak energy [6], giving crystallite diameter of 3,3 nm for 1,85 eV PL peak.

IV. Conclusion

We have demonstrated the ability to prepare porous poly-Si samples on LPCVD boron delta-doped poly-Si substrates. Useful range of anodisation parameters for preparation of porous poly-Si samples was determined. It is believed that PL efficiency can be significantly improved with careful choice of anodisation parameters.

Abstract - We present an interim report on the investigations of the Ta_xN thin films deposited on the (100) Si wafers coated with a 140-nm thermal SiO_2 layer. Our conclusions are based on the room temperature sheet resistance measurements, transport properties measurements from helium up to room temperature and on the Raman spectra analysis of the investigated series. In particular, we discuss a nonmonotonous concentration dependence of transport properties. This behaviour we attribute to a local minimum in the density of electronic states at the Fermi level calculated for the intermetallic Ta_4N_5 [1]. Such behaviour was not observed in other investigations on the transport properties of Ta_xN found in literature. Also our Raman spectra show some differences compared to other Raman investigations on Ta_xN. We ascribe these and other differences discussed to the substrate properties which were used in the preparation of these thin films. The overall properties of the Ta_xN deposited on the oxidized Si wafers are compared to the properties of the Ta_xN thin films deposited on sapphire.

I. INTRODUCTION

In [2], authors presented investigations on the Ta_xN thin films deposited on sapphire within the concentration range: $0.57 \leq x \leq 1.2$. Among other applications, the system holds promise as a barrier material in NbN-based Josephson junction in superconducting digital circuits [2]. Ta_xN deposited on sapphire exhibits superconductivity below 10 K for about $x \approx 1$.

Our task was to investigate the properties of the Ta_xN thin films deposited on oxidized Si wafers which are much cheaper than the sapphire wafers. In a mass production, a product cost is an imperative along with the properties of a product. Although this work was intended to give answers on a practical problem, there appear some new interesting pure scientific problems which ought to be solved. We present here some of the interesting results obtained in this investigation.

II. DEPOSITION DETAILS

Ta_xN was synthesized in a high-vacuum sputtering system equipped with a dc magnetron sputter gun (model Torus 2C, Kurt Lesker Co.) containing a 99.5%-pure 5.1-cm-diam Ta target. Two types of samples were prepared in the same way. First group are the samples synthesized on the 1 cm^2 sapphire while the second group consists of the samples prepared on the 10.2 cm-diam (100) Si wafers coated with a 140 nm thermal layer [2]. The concentration of Ta in these thin films depends mainly on the partial pressure of N_2 in a gas mixture with Ar and on the temperature of the substrate during the deposition process. In the case of the Si wafers, the gas pressure was 50 mTorr and the partial pressure was varied from 10% to 100% while the temperature was kept constant at 450 °C for the Si samples. One expects that the dynamics of the processes during the cooling down to room temperature is going to be the same for each thin film sample even though the concentration varies.

III. TRANSPORT PROPERTIES

The measurement details of the resistivity and thermopower from helium up to room temperature were described in [1]. The resistivity versus temperature is presented in Figure 1. For all concentrations, the resistivities exhibit nonmetallic temperature dependence. It is interesting that the data can be fitted well in the almost whole temperature range measured by a function of the form:

$$\rho(T)/\rho_{RT} = A + B\exp(-T/T_o) \qquad (1)$$

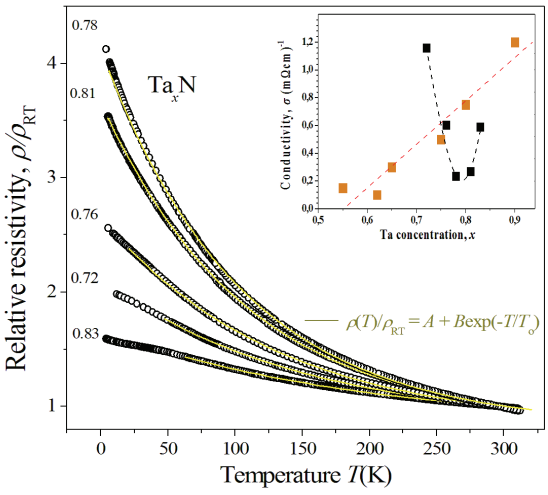

Figure 3 Temperature dependence of the resistivities represented by the relative resistivities $\rho_r(T) = \rho(T)/\rho_{RT}$ of Ta_xN thin films. Open circles are the experimental data while the solid yellow lines are the best fits to the exponential function: $\rho_r(T) = \rho(T)/\rho_{RT} = A + B\exp(-T/T_0)$.
Inset: Conductivities at 200 K. Black closed squares are our data. Black dashed line is only eye guide. Orange closed squares represent the data from [1].

It is rather unusual to fit the resistivity data to the form (1). Although, we have no physical interpretation of this fit and, hence, no physical meaning of parameter T_o, we present the data in this way because T_o is correlated well wit the maximum in the corresponding thermopower [3]. Also, coming from the Jonson-Mahan many-body formalism for charge and thermal conductivity by charge transport [3], we can infer functional form (1) and can describe also the thermopower of Ta_xN but assuming a complicated temperature dependence of the chemical potential.

Temperature dependence of the resistivity data of Ta_xN deposited on sapphire [2] could also be described by (1) (the authors did not try to fit their data). However, the concentration dependence of the resistivity/conductivity of our data and the data in [2] are quite different. In the inset to Figure 1, the conductivities at 200 K, presented with the orange squares, exhibit monotonous and, moreover, a linear behaviour with concentration. The red dashed line is a linear fit of these data and it predicts that the localization happens at $x = 0.55$. This smooth transition towards the zero conductivity indicates that one may consider this localization as the Anderson localization.

Our data, the black squares, show much narrower range of the concentrations where the single rocksalt structure exists and show even a nonmonotonous dependence on concentration. These concentrations are around $x = 0.8$ which we believe is connected to the fact that there exists a stable intermetallic Ta_4N_5. This fact leads to our opinion that the Ta-vacancies in the TaN rock salt structure are not quite randomly distributed but follow the Ta_4N_5 structure.

Superconductivity which exists in Ta_xN deposited on sapphire between 4 and 10 K was not observed in Ta_xN deposited on oxidized Si above 5 K.

IV. Raman Spectra of Ta_xN

SEM analysis of the samples deposited on the sapphire and Si substrates gives that there is no difference among the samples on the scale down to 5 nm. But there exist significant differences on the scale of the mean free path of an electron as suggests the inset to Figure 1. To see the characteristics of the samples in between these scales, we performed Raman spectroscopy of the samples deposited on the oxidized Si wafers. There are only few Raman studies on Ta_xN and there is no Raman spectra analysis for the Ta_xN deposited on sapphire..

Raman spectroscopy measurements were carried out in backscattering geometry using a Horiba Jobin Yvon T64000 spectrometer equipped with the Coherent Innova laser for excitation (514.5 nm line) and a Dilor Z-24 triple monochromator at room temperature.

The Raman spectra are shown in Figure 2. There are three (two of them are very close to each other) maxima which we ascribed, going from low wave numbers, to the first-order transverse acoustic, longitudinal acoustic and optical modes according to [3].

In the crystals with perfect rocksalt structure, the first-order Raman modes are not allowed by the O_h crystal symmetry. As the first-order acoustic and optical bands are observed for all the Ta_xN samples, this indicates the presence of point defects in the rocksalt crystal structure.

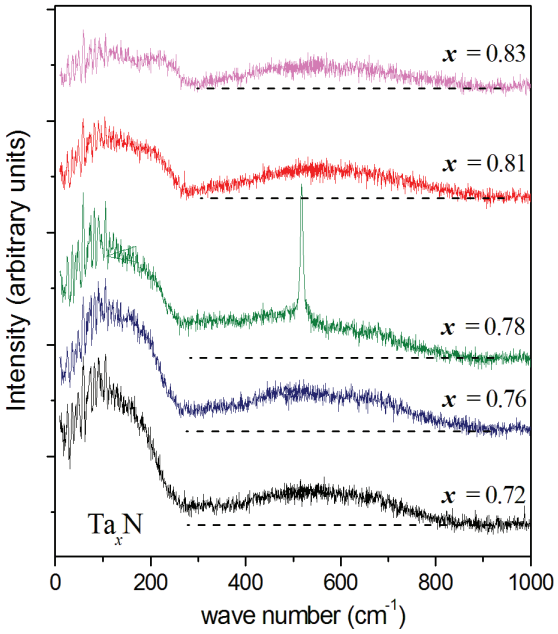

Figure 2 Raman spectra of the Ta_xN thin films. The sharp peak at Ta_xN spectrum belongs to the Si in the wafer.

The main feature of these spectra is the increase of the intensity of the acoustic modes with decrease of the Ta-concentration. We ascribe this behaviour to increase of disorder with increase of the V_{Ta}-vacancy sites. Hence, the N_{Ta}-antisites are missing in the understoichiometric samples.

V. Conclusions

We analyzed the properties of Ta_xN thin films which were deposited at 450 °C on oxidized Si wafers. The main motivation was to investigate a possibility to replace the more expensive Ta_xN thin films deposited on sapphire in various applications and in mass production. Investigations showed much less diversity of the electrical characteristics of the samples deposited on SiO_2 than the ones deposited on sapphire. One of the reasons for this is mainly caused by the narrow range of concentrations where the single phase exists. At this point of the investigation, we are not able to answer why the single phase range is so narrow. We expect that by the deposition at higher temperatures the energy would be enough for formation of N_{Ta}- and Ta_N-antisites for obtaining much wider concentration range and therewith more diverse properties including superconductivity.

Abstract - Even in the metallic regime, heavily doped polycrystalline silicon has high thermopower, but since recently, due its high resistivity combined with high thermal conductivity, silicon was not considered as a possible thermoelectric material. However, various reasons have encouraged investigations on polycrystalline silicon in order to enhance its TE properties. We discuss these reasons and give a short overview of the most promising results and works done in the field. We also present our incipient work on the LPCVD obtained polysilicon thin films annealed in various ways. The main important result we obtained so far is the high thermopower of a Si:B sample: +200 μV/K at room temperature; much higher than predicted for the common metals and the same as of Bi_2Te_3, the only thermoelectric material commercially used nowadays.

I. INTRODUCTION

Thermoelectric (TE) devices are the group of solid state devices that rely on two basic TE effects: Seebeck and Peltier effect. Among others, they can be used in the waste heat conversion making them a valuable weapon in the combat against global warming. At present, their usage is mainly limited by relatively low efficiency of available materials determined through dimensionless figure of merit. At room temperature, the best available thermoelectric devices so far have the figure of merit $ZT = \alpha^2\sigma T/\kappa$ around 1 (Bi_2Te_3). One takes that ZT should be around 3 for TE devices to replace conventional heat pumps and power generators.

We have already presented [1] various materials with pronounced TE properties (one dimensional systems usually have high Seebeck coefficient α, heavy fermion systems have high electrical conductivity σ and materials with particle inclusions are characterized with low thermal conductivity κ).

Some of the materials that could be used in the field of thermoelectrics would greatly benefit from nanostructuring for which they are generally not suitable and this gives silicon one important advantage. Silicon is an ominpresent cheap material and it is at the very base of all human technology. Standard electronic devices technology is mainly oriented on its processing where silicon nanostructures can be produced on the regular basis.

Some authors [2,3] published their investigations on silicon nanowires where they measured the figures of merit form 0.6 to 1. But Si NWs are generally not suitable for large volume applications. Recently, Ikeda and Saleh [4,5] presented their investigation on ultrathin silicon on insulator (SOI) layers. They observed a local increase in the Seebeck coefficient for concentrations above $3.5\cdot10^{19}$ cm^{-3} (which is for an order of magnitude higher than critical concentration). All of these papers (SOI, nanowires) have monocrystalline silicon as a basis. Polycrystalline silicon is a cheaper solution with electrical conductivity that can reach the value of monocrystalline's (for highly doped samples) and with considerably lower thermal conductivity. Narducci et al presented a work [6] on heavily doped polycrystalline silicon as a TE material and reported a power factor three times higher (13 mW/K) than previously reported in Si nanowires.

II. INVESTIGATION ON SI AS TE MATERIAL

A. Heavily boron doped polycrystalline silicon

The first group consists of 2 samples. Polycrystalline films were deposited in the LPCVD furnace onto the oxidized monocrystalline (111) wafers (t_{dep}=60 min, T_{dep}=750°C). The samples were in-situ doped by BCl_3 ($V_0 \approx 8cm^3$) and the only difference between the samples was the number of fixed volumes of dopant gas flushed in the reactor (sample 1a with 3 x 1 V_0 volumes and sample 1b with 3 x 3 volumes). After the deposition, polycrystalline samples were submitted to the thermal annealing (t_{an}=60 min, T_{an}=1200°C) The thickness of the samples measured by bevel measurements is 2.1 μm. (Sheet resistances and carrier concentrations are ρ_{1a}=31.2 Ω/□, $p_{1a}=2.1\cdot10^{19}$ cm^{-3} and ρ_{1b}=8.9 Ω/□, $p_{1b}=8.5\cdot10^{19}$ cm^{-3})

B. Heavily phosphorus doped polycrystalline silicon

The second group of samples is the group with heavily phosphorus doped polycrystalline samples.

Thin amorphous layers were deposited (LPCVD) at 530°C onto (100) *p*-type silicon wafers by parallel flows of silane and phosphine. Wafers were subjected to rapid thermal annealing (RTA) at 950°C in different time intervals (10, 20, 30 and 45 s for samples 2a, 2b, 2c and 2d). Sample 2b was not produced in the same series and the difference can been seen in the results. In this way, we

achieved sample crystallization and therewith dopant activation. Samples are between 200 and 250 nm thick (Sheet resistances and carrier concentrations are ρ_{2a}=44.3 Ω/□, n_{2a}=2.16·10^{20} cm^{-3}, ρ_{2b}=46.4 Ω/□, n_{2b}=2.08·10^{20} cm^{-3}, ρ_{2c}=43.8 Ω/□, n_{2c}=2.18·10^{20} cm^{-3}, ρ_{2d}=40.8 Ω/□, n_{2d}=2.3·10^{20} cm^{-3}).

C. Results

For comparison, we plotted thermopowers of the samples with highest carrier concentrations from both groups. Thermopower vs. temperature is presented in Fig. 1. We can observe the clear linear temperature dependence of thermopower in a wide temperature range (for sample 2c down to 200 K and for sample 1b in the whole measured range). Linear thermopower behaviour is accompanied by $T^{3/2}$ temperature resistivity dependence. Details and discussion on the thermopower and resistivity behaviour are already published [7,8] or will be published elsewhere.

Figure 2. suggests that the maximum in power factor is located for concentrations 5-10·10^{19} cm^{-3}. The importance of this result comes from the fact that about the same result is obtained for small gaped semiconductors [1]. We obtained the same results for the semiconductors in metallic regime with the Fermi temperature about 700 K

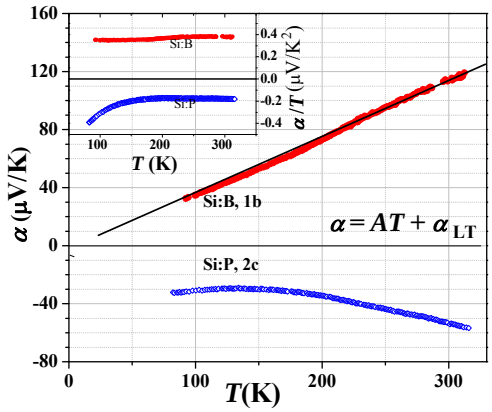

Figure 1. Thermopower/Seebeck coefficient data for two samples from different groups. In the inset α/T is plotted.

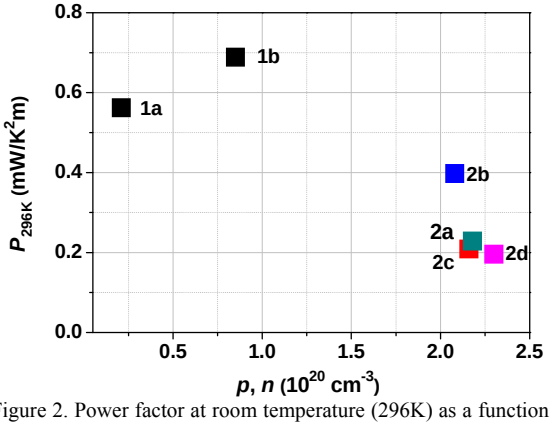

Figure 2. Power factor at room temperature (296K) as a function of dopand concentration is presented. Samples doped with boron have approximately 2 times higher power factor values.

The highest power factor measured was the one for sample 1b, P_{1b}= 7·10^{-4} W/K^{2}m which is 140 times higher than in [9]. With thermal conductivity of κ = 1.3 W/Kcm, figure of merit reaches the value of 1.8·10^{-3}. This value could certainly be 10 to 100 times higher when thermal conductivity of polycrystalline silicon is taken into account.

III. CONCLUSIONS

We present our incipient work on the LPCVD heavily doped polycrystalline silicon thin films prepared in various ways. At present point, our overall investigations show interesting results:

a) For semiconductor, a high TE power factor can be obtained in the metallic regime for dopant concentration from approximately 5 to 10·10^{19} cm^{-3}.

b) In the case of silicon, the corresponding Fermi temperature is around 700 K. One may expect an increase in the *P* value with temperature (up to 700 K). Up to 300 K our measurements show that thermopower increases faster than conductivity decreases.

c) At the present stage of investigation, the *ZT* value of our samples is rather low. Deposting samples at lower temperatures leads to smaller grain sizes with the probable consequence of higher *ZT*.

d) Due to the importance of silicon in the microelectronic industry, achieving the *ZT* value lower than 3 could make it highly competitive (even *ZT* ≈1 could give silicon an enormous advantage in the field of TE devices).

Abstract – **Visible photoluminescence (PL) was observed in binary g-As_2S_3, technologically modified g-$GeS_2(T_iV_j)$ and ternary glasses along $(As_2S_3)_x(GeS_2)_{1-x}$ line. PL maximum in g-As_2S_3 at 2.43 eV was assigned to band-to-band transitions and its position is in good agreement with value of optical band-gap edge absorption (E_0=2.4 eV). It is suggested that the peak at 2.2-2.3 eV in g-$GeS_2(T_iV_j)$ and GeS_2-based ternary glasses may be attributed to presence of GeO_x species. Complex PL peak at 2.6-2.7 eV in GeS_2-based glasses was identified with germanium sulfur sites.**

I. Introduction

Recently the PL results presented in [1-3] show that visible luminescence of the nanostructured Ge thin films originated from the germanium oxide. Nanostructured chalcogenide glasses (ChG) are known to be susceptible to oxide impurities [4]. The extrinsic absorption in Ge-containing ChGS can be caused by non controlled GeO and GeO_2 impurities [4]. Presented here new results of experimental investigation of Ge-free binary g-As_2S_3, g-GeS_2 glass and ternary $(GeS_2)_x(As_2S_3)_{100-x}$ glasses at high energy of PL excitation might add new information about the nature of luminescence in nanostructured materials.

II. Materials and Methods

The binary and ternary glasses were prepared by direct synthesis from appropriate amount of the elements with 5N purity using a standard method. Than the g-GeS_2 samples for PL measuring were synthesized by melt quenching from different temperatures ranging from 1173 K (T_1) to 1473 K (T_4) and quenching rate from 100 K/s (V_1) and 150 K/s (V_2) (hereafter be denoted T_iV_j). The samples were excited by cw laser illumination of 3.03 eV. An exiting diode laser scattering was filtering by cut-of filter at E>2.75 eV. To study the light absorption of these glasses by convenient method, transmittance and reflectance spectra have been used to extract the absorption coefficient (α).

III. Results and Discussion

When the bulk glass of g-As_2S_3 with inclusion of realgar-type As_4S_4 molecules was chosen [5,6] it gives in PL spectrum an intensive narrow symmetric PL signal which maximum is centered at E_1=2.43 eV with low energy side band at E_2=1.7 eV (Figure 1). The excitation energy (3.03 eV) was higher than optical band-gap energy (E_0) of g-As_2S_3 (E_0=2.4 eV). The position of PL maximum E_1 is in good agreement with value of optical band-gap edge absorption E_0 in region of Tauc-rule absorption (Figure1) and LUMO-HOMO energy width of 12-member ring based on $AsS_{3/2}$ pyramids (ΔE=2.41 eV) [7]. Therefore we conclude that luminescence E_1 in g-As_2S_3 originates from band-to-band transitions.

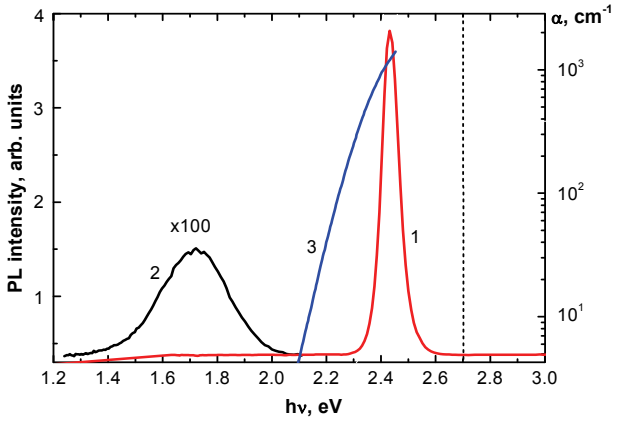

Figure 1. PL and edge absorption spectra of g-As_2S_3: 1,2 - PL; 3 - edge absorption.

The position of a good separated low intensive wide band near E_2=1.7 eV is in excellent agreement with the position of intensive PL band in PL spectrum of natural crystal realgar β-As_4S_4 [8]. Raman scattering measuring performed by varying of excitation photon energy combined with computer simulation experiments in order to obtain detailed images of structure of g-As_2S_3 has shown existing of realgar-type molecules As_4S_4 in g-As_2S_3 [6]. Therefore, we consider in first approximation that E_2 maximum could be connected with realgar-type As_4S_4 molecular inclusions in g-As_2S_3.

Edge absorption spectra of g-$GeS_2(T_2V_2)$ and g-$GeS_2(T_3V_2)$ together with their PL spectra are shown in Figure 2. PL spectra of g-$GeS_2(T_iV_j)$ have on high energy side of wide band almost the same peak position near E^*_1=2.6-2.7 eV, shoulder near E^*_2=2.2-2.3 eV and the tail of each the spectrum is extending beyond 2 eV. The peak position will be indicated E^*_1 and E^*_2 hereafter.

High energy E^*_1 peak position is corresponding to steep rise of the absorption in range of Urbach edge absorption. In order to determine the origin of the low

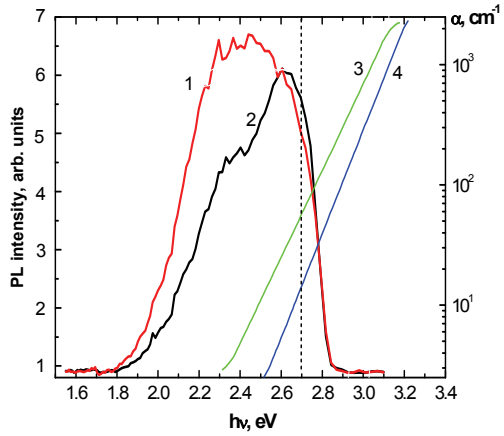

Figure 2. PL and edge absorption spectra: 1,4 - g-$GeS_2(T_3V_2)$; 2,3 - g-$GeS_2(T_2V_2)$

energy E^*_2 photoluminescence spectra of $GeS_2(T_iV_j)$ glasses the luminescence spectra from ternary $(As_2S_3)_x(GeS_2)_{1-x}$ glasses having various Ge to As ratios were examined (Figure 3). With the shift of the optical band gap of $(GeS_2)_x(As_2S_3)_{100-x}$ to lower energy by decreasing x [5], E^*_2=2.2-2.3 eV peak did not change position (Figure 3) but E^*_2 intensity decreases with increasing arsenic content, which indicates that the E^*_2 luminescence in GeS_2-based glasses could be associated with Ge-containing centers. It would be more reasonable to ascribe this peak to presence of GeO_x species like in previous PL studies of nc-Ge [1-3]. The average concentration of oxide impurities in the structure of Ge-containing chalcogenide glasses may be around 10^{-3} mol. % [4,9].

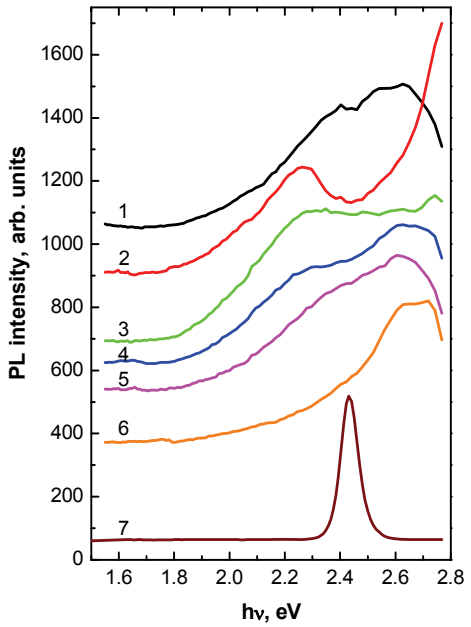

Figure 3. PL spectra of $(As_2S_3)_x(GeS_2)_{1-x}$ glasses: 1) x=0.1; 2) x=0.2; 3) x=0.3; 4) x=0.4; 5) x=0.6; 6) x=0.7; 7) x=0.

Luminescence of unknown origin peaking near E^*_1=2.6-2.7 eV overlaps with E^*_2=2.2-2.3 eV on its high energy side (Figure 2 and 3). High energy PL peak E^*_1 is lying in the region of exponentional part of edge absorption of binary (Figure 1,2) and ternary glasses [5]and could be connected with band-to-band transition. We suggest that this high-energy emission could be due to the presence of some types of Ge_nS_m nanoclusters in native matrix of GeS_2-based glasses. This suggestion based on our findings of increasing intensity of bands connected with 4-member rings in resonant Raman spectra of g-GeS_2 [10]. LUMO-HOMO energy gap for four-member ring is near 3 eV and it is very close to energy of excitation PL of investigated wide band glasses. Role of closed clusters in processes of luminescence in ChGS was theoretically analyzed in [11]. Now experimental investigations of energy structure of wide band glasses are in progress.

IV. CONLUSION

We observed visible photoluminescence in wide band gap binary and ternary chalcogenide glasses. The position of PL maximum in g-As_2S_3 is in good agreement with value of optical band-gap edge absorption E_0=2.4 eV. We assumed that 2.2-2.3 eV visible PL might arise from GeO_x impurities in the structure of GeS_2-based glasses.

Abstract - The variation of the current as function of deformation in the multi-layered graphene films located on the flexible PET-substrate was researched. The current depends on deformation linearly. The gauge factor of the flexible films was calculated. Effect of temperature on conductivity of graphene samples was investigated.

Keywords: graphene, deformation, sensitivity, thin film.

I. INTRODUCTION

Graphene is a single graphite plane in which the sp^2-hybridized carbon atoms form a hexagonal 2D lattice [1]. The chemical methods provide a way to obtain graphene and graphene-like structures from a wide number of materials including expanded graphite, graphite oxide, intercalated graphite compounds, etc [2].

In this paper we used multi-graphene films deposition technology on poly(ethylene terephthalate) (PET) from highly exfoliated graphite [3]. This technology has been shown by J.H. Lee et al [4] and J.H. Shin et al [5].

The goal of the present paper is to research conduction, temperature, and deformation properties of graphene film resistors (GFR).

II. EXPERIMENTAL

Three graphene films on PET with different surface resistances R_{s1}= 9.28 kOhm/sq; R_{s2}= 16.05 kOhm/sq; R_{s3}= 44.36 kOhm/sq were used for GFR's preparation with resistances 102.3 kOhm; 133.2 kOhm and 179.4 kOhm, respectively. The geometry of resistors is rectangular: length l = 10 mm, width w = 1 mm. The length of contact from each side of the resistor is 1 mm. The contacts were made by silver paste. The resistance of the contacts was about 0.02 Ohm and I-V curves of the resistors are ohmic and linear, i.e. electrical contacts with silver paste are ohmic. Since the total resistance of samples was in a range of 0.1 – 0.2 MOhm, then one can neglect the influence of contact resistance.

The GFR-samples were located on the spring steel beam by thin layer of ethyl cyanoacrylate adhesive. The thickness of steel beam is 500 μm, PET-thickness is 100 μm. Since total thickness of GFR-on-PET on the beam is 600 μm, then the thickness of an adhesive is negligible. Moreover the thickness of an adhesive is much less then thickness of PET as well. We consider that adhesive layer provides the rigid fix position of GFR-on-PET on steel beam and value of beam deformation corresponds to value of GFR-on-PET deformation. For experiment we used cantilever beam. The DC voltage was applied to the GFR and variation of the DC current as function of beam deflection was registered.

Thermal characteristics of the graphene films were also obtained. When applying a constant voltage (9.76 V) to the sample, we have obtained dependence of current on temperature. The maximum temperature of 120 ^{0}C was chosen for the softening point of PET (130 ^{0}C).

To estimate gauge factor (S) we used the formula (1) and the high strain of the GFR as follows: $\varepsilon_{high} = 3 \cdot 10^{-3}$.

$$S = \frac{I_0 - I(\varepsilon)}{I(\varepsilon) \cdot \varepsilon_{high}} = \frac{\Delta I}{I(\varepsilon) \cdot \varepsilon_{high}} \qquad (1)$$

III. RESULTS AND DISCUSSION

The deformation characteristics as function of $I(\varepsilon)$ for different samples are shown in Fig.1. The values of S are: S_1=10.7; S_2=14; S_3=16.6. From Fig. 1 one can see that deformation curves are practically linear, i.e. attractive for making of mechanical sensors with linear converter curves. The measurements of current-strain characteristics - $I(\varepsilon)$ for upload and unload of strain are shown that hysteresis is in a frame of experimental error, i.e. 3%.

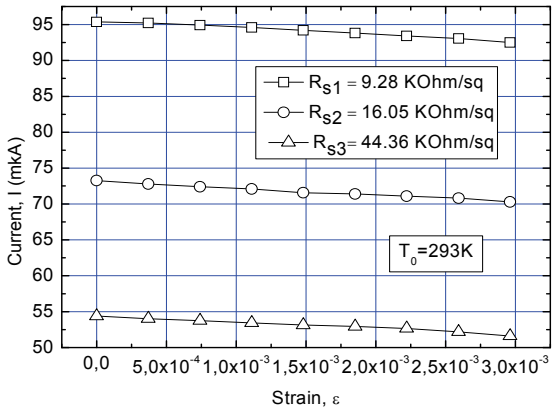

Fig. 1. Deformation characteristics of GFR-on-PET samples at T_0 = 293 K. R_1=102.3 kOhm; R_2=133.2 kOhm; R_3=179.4 kOhm – resistances of unstrained resistors. S_1=10.7; S_2=14; S_3=16.6.

Resistors R_2 and R_3 demonstrate quite high strain gauge factor which is acceptable for sensor's construction. The 1st sample shows the trend in reducing of strain gauge factor for larger thickness of graphene film, but dependence of strain gauge factor as function of film thickness needs in additional research.

We measured the temperature dependence of the current for five different R_s in the un-strained state. All samples shown that dependences *I(T)* are almost linear. It is important to emphasize, that current increases as temperature rises, i.e. resistance comes down. Film resistance oppositely depends on temperature and strain, see Fig. 1. Fig. 2 demonstrates the temperature dependence of the normalized resistance for samples with different surface resistance in a half-logarithmic scale. From the Fig. 2 we can see that the temperature coefficient of resistance of films depends on the surface resistance, hence, the film thickness.

To understand conduction process in film, which consists of many graphene sheets, we are assume, that film has hopping conductivity with variable hopping length.

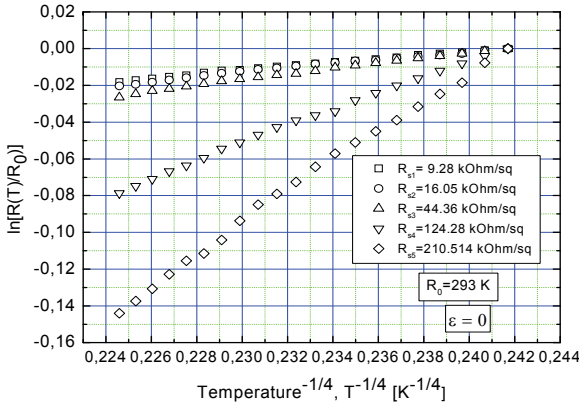

Fig 2. Temperature dependence of the normalized resistance ln[R(T)/R_0] based on VRH model for samples with different surface resistances.

Some amorphous semiconductors (silicon, germanium, carbon, etc.) in the form of films have hopping conductivity with variable hopping (VRH) length. It is observed by Mott in 1968 [6]. By Mott's law, resistivity varies with temperature as follows:

$$\rho(T) = \rho_0 \exp\left\{\left(\frac{T_0}{T}\right)^{1/4}\right\} \qquad (2)$$

where ρ_0 is the resistivity at infinite temperature and T_0 is the characteristic temperature. The VRH model is recently established as the major conduction mechanism by several research groups [7;8]. From Fig. 2 and eq. (2) one can see that film with many graphene sheets fit into the category of materials with hopping conduction.

IV. CONCLUSION

The tensoresistive properties of graphene films of PET have linear type of deformation characteristics – *I(ε)* or *R(ε)*. The strain gauge factor is larger for films with larger surface resistance. The strain gauge factor, *S*, is equal to 10 ÷ 17. This is at least few times more than metal-foil sensors, where *S*≈2. It was also shown that the temperature dependence of the graphene films obeys the Mott's law. The variation of TKR is possible to realize by controlling film thickness, i.e. by variation of initial volume of the solution. We guess that the development of technology for production of graphene films with different thickness will allow get higher strain gauge factor, which should be comparable even with traditional polysilicon strain sensors where gauge factor variates in the range of S = 20÷50 as function of crystallographic orientation.

Abstract - The electronic structures of bulk and single layers dichalcogenides MoX_2 (X = S, Se, Te) were studied by quantum chemistry method of electron localization function (ELF). Three-center interaction between the molybdenum atoms in the layers was found. The nature of this interaction depends on the type of chalcogen X, similar interaction is weaker for $MoTe_2$. The observed effect supposes that observed interaction determines the stability of $MoTe_2$ and may explain the nature of the existence of two structural modifications of $MoTe_2$.

I. Introduction

The transition metal dichalcogenides MX_2 (M = metal; X=S, Se, Te) with layered structure can be considered structurally as strongly bonded two-dimensional X–M–X layers loosely coupled to one another by relatively weak Van der Waals forces. Layered dichalcogenides have attracted many researchers due to their interesting properties like high anisotropic materials, lubricants, matrixes for intercalation compounds and batteries, superconductors, charge density waves, etc. [1-10]. Recently the heightened interest in single-layer transition metal dichalcogenides is appeared again. It was found that exfoliated sheets of MoS_2 have acceptable values of energy band gap and current carrier mobility that is important for design of layered-semiconductor transistors [11].

In this article, we report the results of theoretical study of electronic structures for single layer and bulk molybdenum dichalcogenides MoX_2 (X = S, Se, Te).

II. Calculation Procedures

A. Structures of MoX_2 (X=S, Se, Te)

Molybdenum dichalcogenides MoS_2 and $MoSe_2$ crystallize in trigonal-prismatic 2H-MoS_2 structure, which consists of the alternating infinite triatomic hexagonally arranged layers X-Mo-X constructed from trigonal prisms MoX_6 interconnected by edge sharing (Fig. 1a). Molybdenum ditelluride can adapt two types of crystal structures, namely, 2H-MoS_2 (α-$MoTe_2$ type) and WTe_2 (β-$MoTe_2$ type); in β-$MoTe_2$ structure the octahedra MoX_6 share common edges with formation zig-zag metal chains (Fig. 1b).

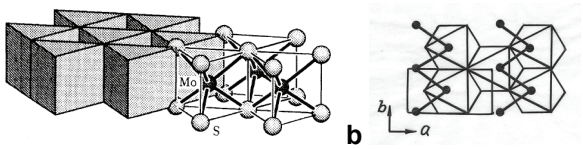

Figure 1. Structure of 2H-MoS_2 (a) and β-$MoTe_2$ (b)

B. Computational Details

Quantum-chemical study of the band electronic structure and distribution of the electron localization function (ELF) [12] in single layers and three-dimensional structures of MoX_2 (X = S, Se, Te) was carried out with a spin-restricted Density Functional Theory method using of VWN&BP/TZ2P (all-electron basis set of STO). Relativistic effects were taken into account with the zero order relativistic approximation - method ZORA. All details can be found in the description of the code ADF BAND 2010 [13].

III. Results

The resulting band structures of molybdenum dichalcogenides are in good agreement with available experimental and theoretical data in the literature [7, 8]. Three-dimensional MoS_2, $MoSe_2$, and α-$MoTe_2$ are indirect-gap semiconductors, and single layer structures are characterized by direct-band gap (see Table 1). Both three-dimensional and single layer β-$MoTe_2$ are conductors.

Table 1. Band gap for MoX_2 (X=S, Se, Te) , eV

	MoS_2	$MoSe_2$	α–$MoTe_2$	β-$MoTe_2$
single layer	1.80	1.52	1.13	0
bulk	0.86	0.86	0.81	0

An unexpected result was obtained from theoretical calculations using ELF method: it was discovered three-center interactions between the molybdenum atoms in single layers and in three-dimensional systems (Figures 2-4).

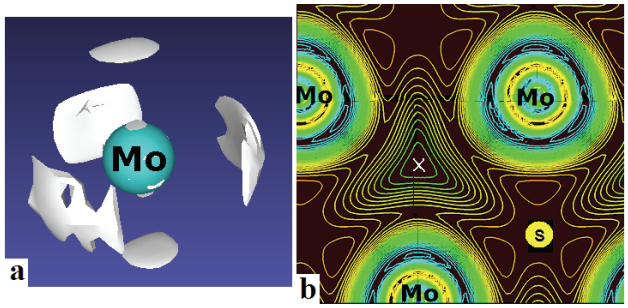

Figure 2. (a) isosurface function ELF (0.75) for the electron density of intra-Mo (4d)-orbitals in the bulk MoS_2 (the location of the three basins in the basal plane, and two basins on the c-axis are show); (b) map of ELF in the basal plane of MoS_2 (sign "x" marked the basins of localization of electron density between the atoms of molybdenum, describing three-center exchange interactions of molybdenum atoms); S - pairs of sulfur atoms, which are located above and below the basal plane. The distance between contours ELF=0.025.

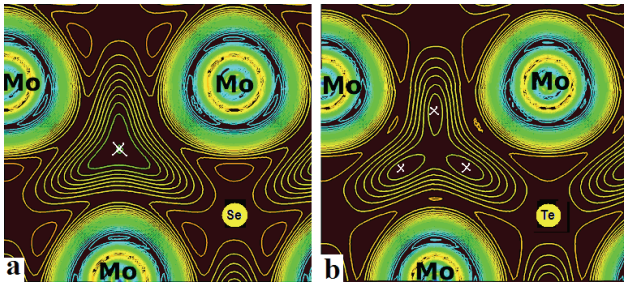

Figure 3. (a) map of ELF in the basal plane of $MoSe_2$ (sign "x" marked the basins of localization of electron density between the atoms of molybdenum, describing three-center exchange interactions of molybdenum atoms); (b) map of ELF in the basal plane of α-$MoTe_2$ (sign "x" marked the basins of localization of electron density between the atoms of molybdenum, to indicate the appearance two-center exchange interactions of molybdenum atoms). The distance between contours ELF=0.025.

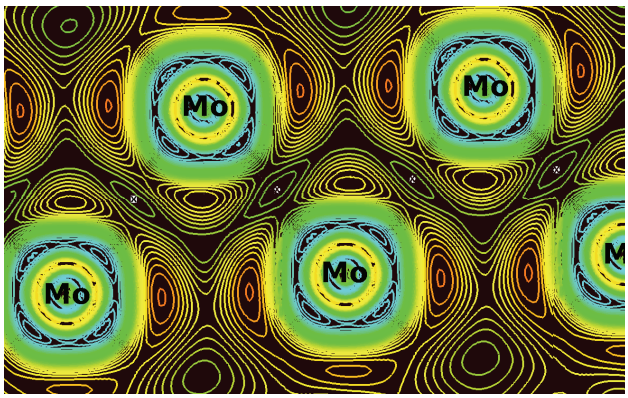

Figure 4. Map of ELF in the plane that contains all Mo atoms of β-$MoTe_2$ (sign "x" marked the basins of localization of electron density between the atoms of molybdenum, describing two-center exchange interactions of molybdenum atoms). The distance between contours ELF=0.025.

At replacing the chalcogen atoms from S to Te the three-center exchange interaction is weakened between the molybdenum atoms and the two-center interaction is enhanced. For α-$MoTe_2$ a nature of the interaction of three-center strives to two-center (Figure 3b). And in the structure of β-$MoTe_2$ it becomes clear two-center interaction (Figure 4).

CONLUSION

Quantum-chemical study (ELF method) of the band electronic structures of MoX_2 (X = S, Se, Te) proposes three-center interactions between Mo atoms in molybdenum layers of 2H-MoS_2 and 2H-$MoSe_2$. In β-$MoTe_2$ two-center metal-metal interaction becomes dominant. Intermediate case is observed in α-$MoTe_2$. We believe that these interactions may be responsible for the stability and electronic properties of layered molybdenum dichalcogenides MoX_2 (X = S, Se, Te).

Abstract – Experimental data of mean values of breakdown voltage $\overline{U_b}$ of CITEL and SIEMENS gas-filled surge arresters (GFSA) obtained for voltage increase rates *k*=1-10 V/s with discretyzed dynamic method are presented in the paper. It has been shown that $\overline{U_b} = f(k)$ data are fitted very well by a straight line. The values of static breakdown voltage, which have been found at the intersection of the fitted line with $\overline{U_b}$ -axis ($k = 0$), are in accordance with nominal values reported in datasheet and within tolerance of 20%. Based on the time delay of electrical breakdown data, it has been shown that the response time of GFSA made by SIEMENS is independent of relaxation time and is 60 μs. Response time of GFSA made by CITEL increases with relaxation time, which is a consequence of the decrease in concentration of positive ions and neutral active particles formed during breakdown. Response time decreases with the increase of applied voltage. This decrease is dependent on relaxation time in the case of GFSA made by CITEL, while this is not the case with SIEMENS made GFSA.

I. INTRODUCTION

The gas-filled surge arresters (GFSA) are non-linear elements used in overvoltage protection. They are known in literature as surge voltage protectors (SVP) or gas discharge tubes (GDT). The main advantages of GFSA, in comparison to other protection components (suppressers diodes and metal oxide varistors), are: the ability to conduct high currents (>5 kA), low intrinsic capacity (<1 pF), high insulating resistance ($>1\,\mathrm{G\Omega}$) and low resistance in conducting regime ($\sim 0.1\,\Omega$) [1-4]. These components are used in overvoltage protection in the range of 70-1200 V. GFSA are mostly used in protective circuits in telecommunications (where overvoltage may arise from different sources including lightning), as well as in high voltage engineering (where switching overvoltage may arise as a consequence of energy redirection within power systems). The main problems in GFSA application are response delay [5], cut off delay when voltage is disconnected and the existence of flow-up current in impulse regime, which is a consequence of GFSA activation by impulse voltage and the ±20% deviation of GFSA activation voltage from nominal values reported in datasheet.

GFSA operation principle is based on electrical breakdown in insulating gases. The voltage at which electrical breakdown occurs is called the electrical breakdown voltage and it is defined as the voltage when discharge in the gas transits from non self-sustaining to self-sustaining mode [6], which is characterized by rapid transition of gas from a poor electrical conductor with a resistance of about $10^{14}\ \Omega\mathrm{m}^{-1}$ to a relatively good conductor [7].

The electrical breakdown in insulating gases can be static or dynamic depending on the type of applied voltage. Static direct current (DC) breakdown occurs when the rate of change of the applied voltage is lower than the rate of change of elementary processes related to electrical breakdown. If these two rates are comparable, the breakdown is dynamic. The static breakdown voltage U_s is a deterministic quantity, whereas the dynamic voltage U_b is a stochastic quantity with a certain distribution [8]. The U_s can not be precisely determined, but only estimated [9].

One thing common for all gas-filled devices, including the GFSA, is the delay of electrical breakdown, which is present even when applied voltage is higher than breakdown voltage. The time which passes between the moment of application of voltage higher than breakdown voltage and the moment when GFSA current starts to flow is called the time delay of electrical breakdown t_d . Response delay of GFSA is a consequence of electrical breakdown time delay, which consists of the statistical time delay t_s and formative time t_f , i.e. $t_d = t_s + t_f$ [7]. t_s is the time which passes from the moment of voltage application on GFSA until the appearance of an electron which leads to breakdown. During this period a small current flows through the tube (10^{-19}-10^{-8} A) but its fluctuations are of the same order as the current itself. The formative time t_f is the time taken from the end of the statistical time to the onset of breakdown, characterized by the collapse of the applied voltage and a self-maintained glow [7]. t_d is dependent on various parameters, but one of the most significant ones is the relaxation time τ , i.e. the time interval between two successive measurements when there is no voltage on the GFSA [10]. Based on functional dependence $\bar{t}_d = f(\tau)$ (memory curve), the presence of active particles responsible for the initiation of subsequent breakdown can be monitored, i.e. the memory

effect in gas, which is responsible for time delay of GFSA, can be tracked.

II. EXPERIMENT

The measurements of time delay of electrical breakdown were conducted with commercial GFSA made by SIEMENS and CITEL. These components have two flat electrodes which are sealed in ceramic housing. The cross section of these components is presented in Fig. 1. The manufacturers haven't disclosed the data of insulating gas type and pressure, although noble gases are most frequently used as an insulating medium. SIEMENS made GFSA have a small radioactive source built into the housing which supplies a constant electron yield (the number of generated electrons in the inter-electrode space per time unit) in order to decrease the response time. Static breakdown voltage (DC spark-over voltage) of these components reported by manufacturers is 230 V with ±20% tolerance and it was obtained for voltage increase rate of 100 V/s. On the other hand, the dynamic breakdown voltage (impulse spark-over voltage) is less than 750 V and this value was obtained for voltage increase rate of 1 kV/ μs .

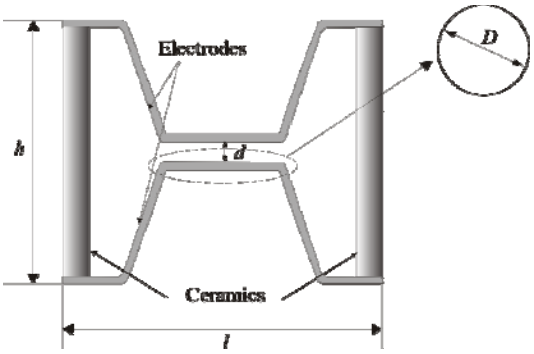

Fig.1: GFSA cross section

The breakdown voltage was measured using the discretized dynamic method, i.e. method of DC voltage increase in step U_p for defined duration of the step t_p until breakdown. Voltage source for this system is a serial connection of two Keithley models 248 and 2400. The control of these two voltage sources is performed by personal computer PC via IEEE standard interface bus. PC sends the starting voltage value U_0, which is considerably lower than expected breakdown voltage value, and this voltage is applied to the tube over Keithley model 248. Starting voltage level is increased for the value U_p every predefined time interval t_p.. The duration of time step t_p is controlled by counter timer model ED2300-CT, which is a part of acquisition card ED2001. In order to provide the accurate breakdown detection, the current flow through device under test is monitored with A/D module of ED2001. Namely, Keithley model 248 has the output which gives the voltage value in the range from 0 to 10 V, which corresponds to the current in the range 0 to 5.25 mA. After breakdown it is necessary to maintain stable glow discharge in the tube. This is achieved by application of constant value U_c for a predefined time interval. After discharge GFSA is disconnected from power supply for the duration of the afterglow period, which is also controlled by ED2300-CT counter/timer module (see [11] for more details).

Measurements of electrical breakdown time delay t_d were performed with the system which consists of DC power supply, analog and digital subsystem. Analog subsystem should provide accurate and fast voltage switching on the GFSA. For this purpose we have used IRG4PH40KD bipolar transistor with isolated gate. The switching is controlled by command signals from digital subsystem over TC429 MOSFET driver circuit. Such system configuration provides satisfactory results regarding the accuracy, reliability and performance of time delay measurements. Roughly, the digital subsystem main function is to give measurement start signal, which controls the switching transistors and applies the voltage on the tube. The voltage pulse on the tube is shaped by the analog subsystem in the form suitable for detection by digital subsystem. Upon its detection time delay measurement is finished. The main part of digital subsystem is the microcontroller. The signals for the beginning and the end of time delay are detected on digital impulse pins, while the time interval between them is measured using standard timer interrupt routines with the use of 16-bit timer module. In order to perform accurate measurement CCP (capture/compare/PWM) module of the microcontroller is incorporated in the whole procedure (see [12] for more details).

III. RESULTS AND DISCUSSION

The dependencies of the mean values of breakdown voltage $\overline{U_b}$ on the voltage increase rate $k = U_p / t_p$ for SIEMENS and CITEL GFSA are displayed in Fig. 2. $\overline{U_b}$ was established from a series of 100 measurements of U_b data for each value of k. U_p values were varied from 0.1 to 1 V, while t_p was 0.1 s, which corresponded to voltage increase rates from 1 to 10 V/s. It can be seen that $\overline{U_b}$ increases for less than 1 V as k increases and that experimental results are fitted well by a straight line. The values of static breakdown voltage obtained at the intersection of the fitted lines and $\overline{U_b}$ axis for SIEMENS and CITEL GFSA are 250 and 245 V, respectively. These values are in good agreement with nominal values of $230\ \text{V} \pm 20\%$ given by manufacturers.

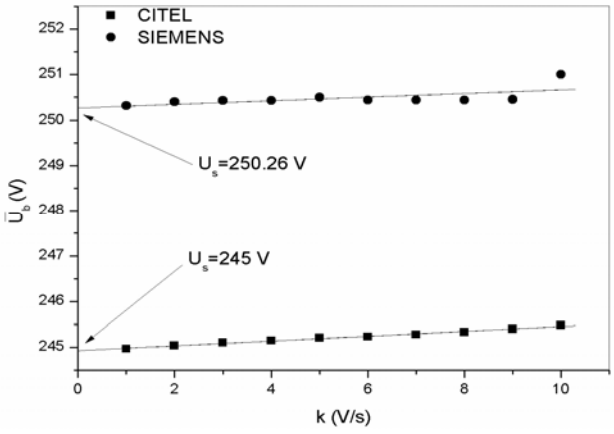

Fig. 2: Mean value of breakdown voltage $\overline{U_b}$ as a function of voltage increase rate k for SIEMENS and CITEL GFSA.

The dependencies of the mean value of time delay of electrical breakdown $\bar{t}_d$ on the relaxation time τ (memory curve) for SIEMENS and CITEL GFSA are shown in Fig. 3. $\bar{t}_d$ is the mean value of a 100 t_d data obtained for each value of τ. t_d data has been obtained when voltage impulses were 300 V. As can be seen from Fig. 3, for SIEMENS made GFSA $\bar{t}_d$ has approximately constant value of about 60 μs for all values of relaxation time. This shows that processes which occur in gas in SIEMENS made GFSA during discharge have no influence on the following breakdown since breakdown initiation is conditioned by electron yield caused by radioactive source. Based on the behavior of the memory curve of the SIEMENS made GFSA it can be concluded that response time of these components is entirely determined by the time needed for avalanche formation, which is, in this case, 60 μs.

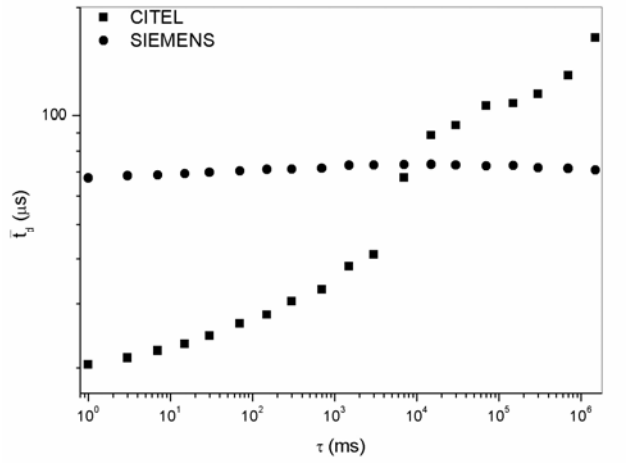

Fig. 3: Mean value of electrical breakdown time delay $\bar{t}_d$ as a function of relaxation time τ for SIEMENS and CITEL GFSA

The shape of the memory curve of CITEL made GFSA is more complex than SIEMENS's which is a consequence of the change of electron yield with the increase in τ. Namely, the electron yield in CITEL GFSA originates from electrons released from electrodes by ions and neutral active particles formed during and after breakdown. Recombination/de-excitation time of these particles differs and insulator gas "remembers" that breakdown has occurred in it. This shows that response time of CITEL made GFSA depends on the type of particles which have a dominant influence on electron yield in the inter-electrode gap. Since in the region $1\text{ ms} < \tau < 1000\text{ ms}$ $\bar{t}_d$ increases from 20 to 40 μs it can be concluded that electron yield originates from positive ions formed during and after breakdown (the mechanisms of positive ions formation and their contribution to electron yield is described in details in [13]). For $\tau > 1000$ ms electron yield originates from neutral active particles formed during breakdown and the mechanisms of their creation are also described in [13]. The probability of secondary electron release from the cathode by neutral active particles impact is much lower than probability of release by ions, which is manifested by the increase in $\bar{t}_d$ (increase of response time of GFSA). The concentration of neutral active particles decreases with the increase of τ due to their de-excitation on the housing walls and electrodes, which leads to decrease of the electron yield and increase in $\bar{t}_d$. As can be seen in Fig. 3, the memory effect of CITEL made GFSA is present even at $\tau > 10^5$ ms (memory curve has not reached saturation), which leads to conclusion that this components are less reliable than SIEMENS GFSA in overvoltage protection.

$\bar{t}_d$ dependencies on the applied voltage impulse for SIEMENS and CITEL GFSA are displayed in Figs. 4 and 5, respectively. These dependencies have been obtained for relaxation times of 3, 300 and 3000 ms. It can be seen from Fig. 4 that the increase of voltage impulse from 240 to 250 V leads to the decrease in $\bar{t}_d$ for one order of the magnitude (response time is also decreased for an order of the magnitude), while $\bar{t}_d$ has a much slower decrease rate for larger values of applied voltage impulse. With SIEMENS GFSA $\bar{t}_d$ is practically independent from τ. This confirms our conclusion that electron yield originating from the radioactive source has a main role in breakdown initiation, while memory effect contribution can be neglected.

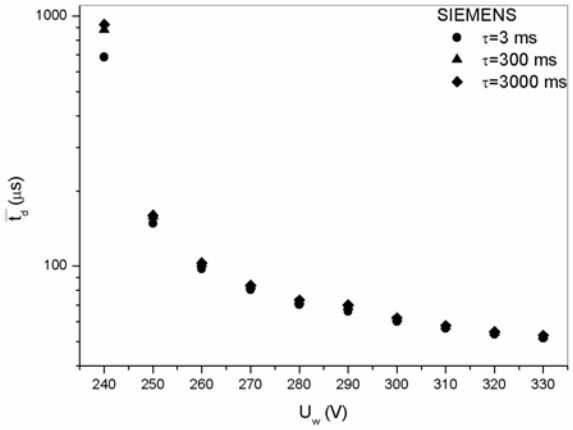

Fig. 4: Mean value of electrical breakdown time delay $\bar{t}_d$ as a function of applied voltage U_w for SIEMENS GFSA

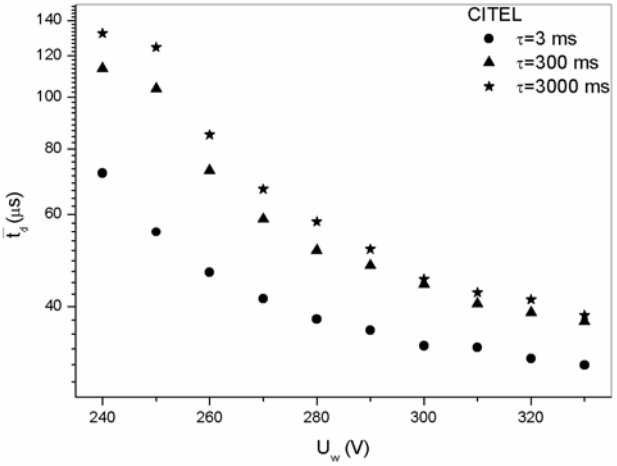

Fig. 5: Mean value of electrical breakdown time delay $\bar{t}_d$ as a function of applied voltage U_w for CITEL GFSA

$\bar{t}_d$ values of CITEL GFSA decrease with the increase of voltage impulse also (Fig. 5). However, the curves shift towards higher values of $\bar{t}_d$ with the increase in τ. The increase of $\bar{t}_d$ with the increase in τ is in accordance with our conclusion that electron yield originates from particles formed during breakdown which decrease in concentration during afterglow period thus reducing the electron yield and increasing $\bar{t}_d$.

IV. CONCLUSION

On the basis of the above written consideration, the following can be concluded. The static breakdown voltage, as a deterministic quantity, can very precisely be estimated by fitting the dependence of mean value of the electrical breakdown voltage on the voltage increase rate. The values of static breakdown voltage obtained in this manner are in good agreement with nominal values reported by manufacturers and within their tolerance range of ±20% . The response time of GFSA can be estimated based on experimental data of time delay of electrical breakdown. The estimated value of SIEMENS GFSA response time is 60 μs and this value is independent of relaxation time. This is due to the fact that the dominant contribution in breakdown initiation has a constant yield originating from radioactive source placed into the components housing. The response time of CITEL made GFSA increases with relaxation time, which is a consequence of the decreasing concentration of particles which contribute to electron yield in the inter-electrode space. Response time of SIEMENS GFSA decreases with increase of applied voltage and is practically independent of relaxation time.

Finally, it should be pointed out that although SIEMENS GFSA have somewhat better characteristics regarding the response time, their main drawback is the negative effect of the radioactive source on the environment.

Abstract – Gamma-ray irradiation and post irradiation response at room and elevated temperature have been studied for RADFETs with gate oxide thickness of 100 nm with gate polarization during irradiation of 5 V as well as for RADFETs with gate oxide thickness of 400 nm with gate polarization of 0, 2.5 and 5 V. The response was observed on the basis of threshold voltage shift, ΔV_T . Approximately linear dependence between ΔV_T and absorbed dose was established. During the annealing at room temperature the RADFETs with the gate thickness of 400 nm and the gate polarization during irradiation of 2.5 V and 5 V shows the tendency in ΔV_T decrease, while for 400 nm RADFETs with the zero gate polarization during irradiation and 100 nm RADFETs ΔV_T remains approximately unchanged. Continued annealing at 120 °C leads to the decrease of ΔV_T . For 100 nm RADFETs, ΔV_T decreases to zero while for 400 nm RADFETs such decrease is considerably smaller.

I. INTRODUCTION

Radiation sensitive Al-gate p-channel MOSFETs (also known as RADFETs, or pMOS dosimeters) have been developed for applications such as space, nuclear industry and radio therapy [1-3]. Other types of dosimeters that are commonly used for these applications include thermo luminescent dosimeters, semiconductor diodes and optically stimulated luminescence dosimeters. The thermo luminescent dosimeters are rather small, well characterized and standard in use; however, they are not suitable for remote measurements and the readout of dosimetric information is destructive. Semiconductor diodes are also miniature in size, but they produce small dosimetric signal and require high voltage. Optically stimulated luminescence dosimeters require integration of electronic and optic elements in the readout system and the readout of dosimetric information is destructive. The RADFET advantages include immediate, non-destructive readout of dosimetric information, small size, and very low power consumption, all-electronic interfaces fully compatible with microprocessors, high dose range and very competitive price. The RADFET disadvantages are a need for calibration in different radiation fields, relatively low resolution (starting from about 1 Gy) and non-reusability. A new design approach have been investigated recently in order to overcome the low resolution problem and to introduce the RADFETs into personal dosimetry area.

The basic concept of RADFET is to convert the threshold voltage shift, ΔV_T , induced by gamma-ray irradiation into absorbed dose D. This dependence can be expressed in the form [4]

$$\Delta V_T = AD^n , \quad (1)$$

where A is the constant and n is the degree of linearity which depends from electric field, oxide thickness and absorbed radiation dose. Ideally, the dependence should be linear, i.e. $n=1$ and in that case A represents sensitivity, S of RADFETs:

$$S = \frac{\Delta V_T}{D} . \quad (2)$$

Irradiation leads to the creation of positive gate oxide charge and interface traps at Si/SiO_2 interface. Both the positive gate oxide charge and interface traps in p-channel MOSFETs contribute to the ΔV_T in same direction and this fact is one of the main reasons for transistor application as a detector of absorbed dose of gamma irradiation. The RADFETs must satisfy two fundamental demands: a good compromise between sensitivity to irradiation and insignificant recovery at room temperature after irradiation, i.e. the information about radiation dose must be preserved over time.

II. EXPERIMENT

The experimental samples were RADFETs manufactured by Tyndall National Institute, Cork, Ireland [5]. Oxide thickness was 100 and 400 nm, and they were grown at 1000 °C in dry oxygen and annealed for 15 minutes in nitrogen. The post-metallization anneal was performed at 440 °C in forming gas for 60 minutes.

Irradiation was performed in the Metrology Laboratory of the Vinca Institute of Nuclear Science, Belgrade. The RADFETs were irradiated at room temperature using $^{60}_{27}Co$ source up to absorbed dose of 35 Gy(Si) at absorbed dose rate of 0.002 Gy(Si)s^{-1}. The gate polarization, V_{irr} , during irradiation of RADFETs with the gate oxide thickness of 400 nm was 0, 2.5 or 5 V, while for the samples with oxide thickness of 100 nm polarization was 5 V (all other pins were grounded). After irradiation the samples were annealed at room temperature

for 218 days without polarization (all pins were grounded). After that, the annealing was continued at elevated temperature of 120 °C also without gate polarization for 15 days.

The change in threshold voltage shift ΔV_T due to gamma-ray irradiation and annealing can be expressed as [6]

$$\Delta V_T = \Delta V_{ot} + \Delta V_{it} \ , \qquad (3)$$

where ΔV_{ot} and ΔV_{it} are contributions to the change in threshold voltage due to the positive oxide charge and interface traps, respectively. ΔV_{ot} and ΔV_{it} can be expressed as a function of areal density of positive gate oxide charge ΔN_{ot} and areal density of interface traps ΔN_{it} [7]

$$\Delta V_{ot} = \pm \frac{q}{C_{ox}} \Delta N_{ot} \, , \Delta V_{it} = \frac{q}{C_{ox}} \Delta N_{it} \ . \qquad (4)$$

In the above expression, the upper sign refers to n-channel MOSFETs and the lower sign refers to p-channel MOSFETs (the absolute value of p-channel MOSFETs threshold voltage is given throughout the paper), C_{ox} is the gate capacitance per unit area and q is absolute value of electron charge.

In order to detect the radiation and post irradiation response, the RADFETs transfer characteristics were measured, and the threshold voltage was determined as the intersection between V_G axis and extrapolated linear region of $(I_D)^{1/2} - V_G$ curve. The sub threshold charge separate technique (MGT) [7] was used to determine ΔN_{ot} and ΔN_{it} in the expression (4).

The I-V characterization was performed by Keithley 4200 SCS (Semiconductor Characterization System). The system is equipped with three medium power source measuring units (4200 SMU) for I-V characterization. The source measuring units have four voltage ranges: 200 mV, 2V, 20 V and 200 V, while the current ranges are 100 μA, 1 mA, 100 mA and 1A. One of the source-measuring units is equipped with a preamplifier which provides the measurements of very small currents (in the order of 1 pA).

To illustrate the influence of irradiation on RADFETs behavior in Figure 1 we have plotted transfer characteristics in saturation before irradiation (curve (0)) and after irradiation for absorbed dose of 35 Gy(Si). The threshold voltage shift ΔV_T can be expressed as $\Delta V_T = V_T - V_{T0}$, where V_{T0} is the threshold voltage before irradiation and V_T is the threshold voltage after irradiation (in Figure 1 V_T is the threshold voltage after absorbed dose of 35 Gy). During annealing V_T represents the threshold voltage after determined time of annealing at room or elevated temperature.

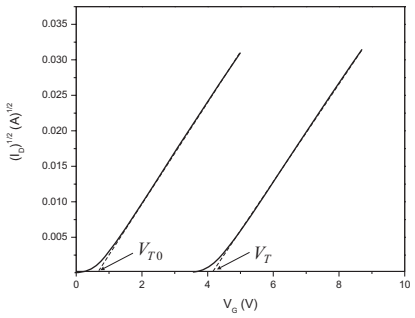

Figure 1. Transfer characteristics and values of threshold voltage shift before irradiation (V_{T0}) and after irradiation of 35 Gy when $V_{irr} = 5\,\mathrm{V}$ (V_T) for RADFET with 400 nm gate oxide thickness.

III. RESULTS AND DISCUSSION

Figure 2a gives $\Delta V_T = f(D)$ dependence of RADFETs with gate thickness of 400 nm for V_{irr} 0, 2.5 and 5 V. It can be seen that ΔV_T strongly depends on V_{irr} values during irradiation. For example, for the dose of 35 Gy the ratio of ΔV_T for $V_{irr} = 2.5\,\mathrm{V}$ and $V_{irr} = 0\,\mathrm{V}$ is about 2.7 V, while for $V_{irr} = 5\,\mathrm{V}$ and $V_{irr} = 0\,\mathrm{V}$ the ration is about 4.2. It can be concluded that the polarization on the gate can cause significant influence on the range of measured gamma-ray dose. Namely, with the increase of gate polarization the threshold voltage shift is higher for the same irradiation dose, what can drive the RADFET away from the area of linear dependence between threshold voltage shift and irradiation dose and also transistor is much more likely to fail. Doses used in our experiments are relatively small so they don't lead to significant degradation of RADFETs, i.e. there is approximately linear dependence between ΔV_T and D.

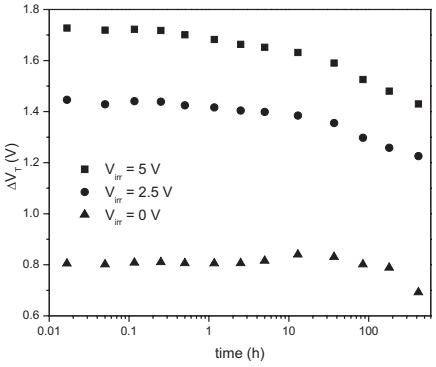
b)



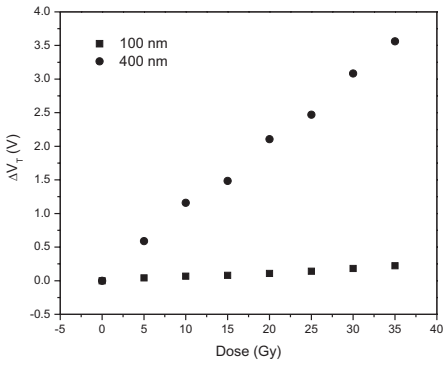
c)

Figure 2. Threshold voltage shift ΔV_T during a) irradiation, b) spontaneous annealing and c) annealing at 120 ºC for RADFETs with 400 nm gate oxide thickness and gate polarization of 0, 2.5 and 5 V.

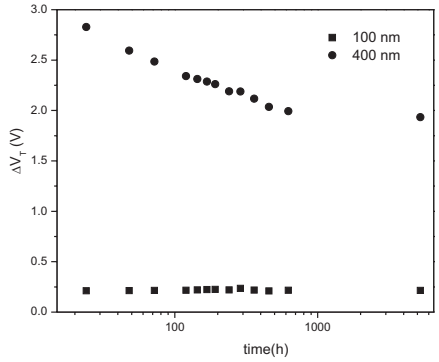
Figure 3a presents $\Delta V_T = f(D)$ dependence for RADFETs with 100 and 400 nm thick oxide, respectively with the gate polarization of $V_{irr} = 5\,\mathrm{V}$. It can be seen that there is also approximately linear dependence between ΔV_T and D for RADFETs with the 100 nm oxide thicknesses, but these values are smaller than for RADFETs with the 400 nm oxide thicknesses. This shows that the sensitivity to gamma irradiation is bigger for RADFETs with thicker gate oxide due to larger density of positive oxide charge and interface traps for the same value of absorbed dose.

Presented experimental results (figures 2a and 3a) can be most readily explained on the bases of the model proposed by Lelis and coworkers (DHL model) [8-10]. The crucial role in this model belongs to E_γ' center, which is a weak Si – Si bound in the oxide caused by an oxygen atom vacancy between two Si atoms, each back-bonded to three oxygen atoms [11]. The E_γ' center act as a hole trap and it is predominantly responsible for the increase of oxide trapped charge during irradiation [12]. The oxide trapped charge involves both charge trapped at fixed oxide traps (FT) and the charge trapped at switching oxide traps (SW). FT represents traps created in the gate oxide that do not capture the carriers from the channel of RADFETs. ST represents the traps created near and at Si/SiO_2 interface and they do capture (communicate with) the carriers from the channel within the time frames of electrical (MGT) measurements [7]. The ST created in the oxide near Si/SiO_2 interface are called slow switching traps (SST), but the ST created at the interface are called fast switching traps (FST). We accept the convincing arguments presented in [10] that the irradiated oxides are E_γ' centers close to Si/SiO_2 interface. The FT are E_γ' centers, which are located further from Si/SiO_2 interface and hence incapable to exchange the charge within the time frame of the measurement. The number of created FT and ST rises with the number of holes which have avoided the recombination with electrons. For $V_{irr} = 0\,\mathrm{V}$ electric field in the oxide is only due to the work function difference between the gate and the substrate (zero bias condition is equal to the gate bias of 0.3 V), so the probability for electron-hole recombination is higher than in the case when $V_{irr} > 0\,\mathrm{V}$. For higher V_{irr}, large number of holes will escape the initial recombination, what further increases the probability for their capture at E_γ' centers and increase of ST. This leads to the increase of ΔV_T during irradiation (figures 2a and 3a). The densities of FT and ST are for the same gate polarization and irradiation dose higher for thicker gate oxide what is manifested in higher ΔV_T (figure 3a).

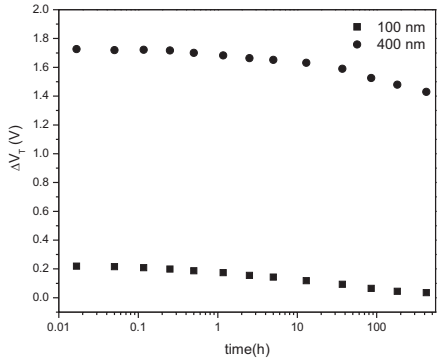
The defects at the Si/SiO_2 interface, known as fast switching traps (FST or true interface traps) represent an amphoteric defect known as P_b center [13], which is a silicon atom at the Si/SiO_2 interface back bonded with three silicon atoms from the substrate. They can be created by trapping holes [14, 15] (h^+ model) and by hydrogen released in the oxide (hydrogen-released species model known as H-model) [16, 17] Both models includes the increase of P_b centers (increase of ΔN_{it}) with the increase of gate polarization during irradiation. Our recent investigations [18] have shown that for RADFETs considered in this paper $\Delta N_{it} \approx 0.1 \cdot \Delta N_{ot}$. So, FT and SST have dominant role to ΔV_T value and further influence of ΔN_{it} to ΔV_T will be excluded.



a)



b)



c)

Figure 3. Threshold voltage shift ΔV_T during a) irradiation, b) spontaneous annealing and c) annealing at 120 ºC for RADFETs with 100 and 400 nm gate oxide thickness and gate polarization $V_{irr} = 5\,\mathrm{V}$.

Figure 2b presents ΔV_T evaluation during annealing at room temperature (spontaneous recovery) of irradiated RADFETs with the gate thicknesses of 400 nm for the duration of 218 days. It can be seen that the rate of dosimetric information loss (fading), i.e. the rate of ΔV_T decrease in the early phase of spontaneous recovery depends on V_{irr} values during irradiation. For bigger V_{irr} values the rate of ΔV_T decrease during annealing is higher. For RADFETs with $V_{irr} = 0\,\mathrm{V}$ during irradiation, ΔV_T remains approximately constant, while for RADFETs with $V_{irr} = 2.5\,\mathrm{V}$ and $V_{irr} = 5\,\mathrm{V}$, ΔV_T decreases during spontaneous recovery during 1000 h, and after that period of time it remains approximately constant.

Figure 3b presents ΔV_T evolution during spontaneous recovery for RADFETs with gate oxide thickness of 100 and 400 nm which were irradiated with gamma ray radiation up to 35 Gy and with $V_{irr} = 5\,\mathrm{V}$ gate polarization. It can be seen that ΔV_T insignificantly changes during spontaneous recovery for RADFETs with 100 nm gate thickness, i.e. the dosimetric information is saved over time.

The ΔV_T behavior during spontaneous annealing (figures 2b and 3b) is also consistent with HDL model. Namely, under electric field in the oxide due to the work function difference between gate and the substrate during annealing, the hole trapped at E_γ' center can either be compensated or neutralized by the electron tunneling from Si. On the bases of ΔV_T behavior (figures 2b and 3b) it can be concluded that the loss of dosimetric information depends on V_{irr} and oxide thickness. Namely, during irradiation of RADFETs bigger concentration of FT and ST traps is formed for higher gate polarization what further leads to higher loss of dosimetric information (fading). Also, for thicker gate oxide the concentration of these traps is bigger what leads to the dosimetric information loss for shorther time.

In order to determine whether the process of dosimetric information loss is finished after spontaneous annealing, the annealing is continued at the temperature of 120 ^{o}C for the 15 days. The threshold voltage shift, ΔV_T , during such annealing for RADFETs with gate oxide thickness of 400 nm and gate polarization of 0, 2.5 and 5 V, is presented in figure 2c. It can be seen that the changes in ΔV_T for RADFETs with gate polarization of 2.5 and 5 V are much smaller than the changes in the beginning of spontaneous annealing.

The continuation of annealing at 120 ^{o}C for RADFETs with 100 and 400 nm oxide thickness and gate polarization of $V_{irr} = 5\,\mathrm{V}$ is presented in figure 3c. It can be seen that for the time of 15 days RAFETs with 100 nm gate thickness loses all of the dosimetric information. For RADFETs with 400 nm gate thickness loss of dosimetric information is very small. The continuous decrease of ΔV_T during annealing at 120 ^{o}C is probably a consequence of neutralization/compensation of the part of E_γ' centers by electrons, which are thermally emitted from the oxide valence band [19]. On the bases of ΔV_T values behavior (figure 3c) it can be concluded that this process is dominant for RADFETs with 100 nm gate thickness. The reason for such behavior is probably higher electrical field in gate oxide during annealing for RADFETs with 100 nm gate thickness.

IV. CONCLUSION

Gamma-ray irradiation and post-irradiation response of RADFETs with 100 nm and 400 nm thick oxides have been investigated. The response of studied devices was observed on the basis of threshold voltage shift determined from transfer characteristics in saturation. The results shows that for the doses up to 35 Gy sensitivity can be expressed as the ratio between threshold voltage shift and absorbed dose and that such approximation for RADFETs with 400 nm gate thickness is better for higher value of gate bias applied during irradiation. The sensitivity for RADFETs with 100 nm oxide thickness and 5 V gate polarizations during irradiation can be expressed in the same manner. This shows that these components can be useful as sensors of high dose range of gamma-ray irradiation. However, RADFETs with gate thickness of 400 nm are more suitable as sensors because they exhibit higher threshold voltage change during irradiation. During spontaneous annealing for RADFETs with 100 nm gate thickness, threshold voltage shift remains approximately constant, i.e. at room temperature dosimetric information is preserved for the time of 218 days. For RADFETs with 400 nm gate thickness irradiated under gate polarization of 2.5 and 5 V, during 50 days spontaneous annealing threshold voltage shift decreases, i.e. a part of dosimetric information is lost. The continued annealing at $120\,^{o}\mathrm{C}$ leads to complete loss of dosimetric information for RADFETs with 100 nm gate thickness while such loss is partial for RADFETs with 400 nm gate thickness. $E_{\gamma}^{'}$ centers play a crucial role in the RADFETs response, being responsible for both fixed and slow switching traps influence to threshold voltage shift during irradiation and annealing. This influence is much bigger than the influence of fast switching traps. Because of that, the knowledge about the behavior patterns of fixed traps and slow switching traps is crucial in RADFETs optimization during gamma-ray irradiation and post-irradiation annealing.

Abstract – Diodes fabricated by a pure amorphous boron (PureB) deposition technology show outstanding performance. Depositing a PureB-layer on Si at temperatures from 500 - 700ºC creates an effective p^+-layer at the interface and ultrashallow p^+n-junctions less than 10 nm deep can be made. The PureB layer can also be used as an emitter region in *pnp* bipolar transistors having a high effective emitter Gummel number (G_E) that appears to be related to the properties of the amorphous boron layer. In this paper, we suggest a wide-bandgap model of the amorphous boron layer to explain how its properties can lead to a suppression of the electron injection from the base into the emitter region thus giving the high G_E. The presence of trap states in the bandgap of amorphous boron layer is also considered. They could reduce the majority carrier concentration and change the mobility in the layer contributing to a decrease of G_E. It is concluded that the wider bandgap together with the trap states in the bandgap of amorphous boron layer could account for the high emitter Gummel number.

I. INTRODUCTION

In PureB technology a layer of amorphous boron is deposited on Si to form p^+n diodes [1]. Photodiode fabricated in this technology have been demonstrated to have superior performance for applications such as deep-ultra-violet/extreme-ultra-violet radiation detection [2]-[3] and low-energy electron detection [4]. The PureB layer is deposited in commercially available chemical vapor deposition systems. During the deposition, the silicon surface is exposed to diborane (B_2H_6) gas at atmospheric or reduced pressures and at temperatures from 500 °C to 700 °C. Exposure time controls the thickness of the boron layer. An amorphous boron (α-B) layer is deposited on the silicon surface while the reaction of boron atoms with the silicon forms a boron silicide (B_xSi_y) layer at the α-B/silicon interface. When the temperature is high enough the deposited boron layer is also a diffusion source of boron for doping the bulk silicon. However, in all cases, even at 500ºC, ultrashallow p^+n junctions are formed with depths below 10 nm.

Experiments have also been performed where the PureB p^+n junction is incorporated as the emitter region in *pnp* bipolar transistors. The boron layer was deposited at 500° C or 700° C with various diborane exposure times followed by the metallization by an Al/Si (1%) layer. Measurements of emitter Gummel numbers (G_E) of the processed *pnp* transistors [5] show an increase in G_E with B_2H_6 exposure times. The extracted G_E for boron layer *pnp* transistors is comparable to the conventional ion implanted emitter *pnp* transistors. The measured G_E compared to the theoretical G_E extracted from simulations of *pnp* transistors with the emitter region formed only by the B-diffused junction achieved during the deposition is 2 orders of magnitude higher. Large discrepancy between the simulations and the measurements posed questions on the physical mechanisms responsible for the suppression of the electron injection from base to emitter which lead to high G_E. Emitter Gummel number is defined as [5]:

$$G_E = \int_{W_{QNE}} \frac{N_E(z)}{D_n(z)} \frac{n_{i0}^2}{n_{ie}^2(z)} dz + \frac{N_E(z)}{S_E} \frac{n_{i0}^2}{n_{ie}^2(z)}\bigg|_{z=0(\text{contact})}, \quad (1)$$

Here, N_E is the active *p*-type concentration, D_n is the electron diffusion coefficient, n_{i0} is the intrinsic carrier concentration and $n_{ie}(z)$ is the effective intrinsic carrier concentration defined as:

$$n_{ie}(z) = n_{i0} \exp\left(\frac{\Delta E_G(z)}{2kT}\right), \quad (2)$$

where ΔE_G is the bandgap difference compared to the crystalline silicon. $W_{QNE} = W_{\alpha\text{-}B} + W_{BxSiy} + W_{c\text{-}Si}$ is the width of the p-type emitter region composed of α-B, B_xSi_y and c-Si doped with boron and S_E is the recombination velocity at the emitter contact. As reported in [5] the B_xSi_y and B-doped bulk silicon layer do not contribute significantly to G_E, therefore the amorphous boron layer dominates G_E. Influence of S_E in the amorphous boron layer is also negligible since G_E increases with boron layer thickness where S_E is constant.

In this paper, we analyze the influence of physical properties of amorphous boron layer on the electrical characteristics and the effective emitter Gummel number of ultrashallow p^+n junctions and *pnp* bipolar transistors. The amorphous boron layer is modeled by adjusting the bandgap and the distribution of traps in the bandgap with respect to c-Si. Larger bandgap of the amorphous boron

layer results in the formation of heterostructure. Due to the offset in the conduction band, the electron injection to amorphous boron layer can successfully be blocked resulting in G_E increase. Also, the trap states present in the bandgap of the amorphous boron layer serve as a trapping mechanism for electrons and holes. Trapping can result in the reduction of the effective carrier concentration and the decrease of the effective electron mobility in the boron layer leading to G_E change.

II. Properties of Amorphous Boron

The bandgap properties of the nm-thin amorphous boron layer are not known. The bandgap of much thicker amorphous boron films reported in the literature varies between 1.3 eV and 1.7 eV, depending on the process conditions [6]. Process conditions also influence the trap states concentrations in the bandgap of amorphous boron.

The bandgap and the trap states inside bandgap are deduced from the density-of-states (DOS) of a specific material. To the best of our knowledge, the DOS for amorphous boron has not yet been reported. However, DOS of crystalline β-rhombohedral boron is reported in [7]. As defined in [8], "amorphous concept" is used to connect electrical and physical characteristics of crystalline β-rhombohedral boron with those of amorphous boron. Structure elements for both the crystalline β-rhombohedral boron and the amorphous boron are icosahedron (B_{12}) clusters. The unit cell of β-rhombohedral boron is large (10 x 10 x 25 $Å^3$) compared to the interatomic distances (1.7 to 1.9 Å) and contains 105 atoms. Due to the large dimensions and complicated structure, the electrical characteristics of β-rhombohedral boron are determined by the short range order similar as in amorphous semiconductors [8].

One of the commonly used methods for characterization of amorphous semiconductors are time-of-flight (TOF) photoconductivity experiments. TOF experiments are used to determine the carrier drift mobility in the material under test. Drift mobility is calculated from the transit time (t_t) it takes the carriers generated at one end of the sample to traverse through the sample attracted by a constant electric field. Traps in the bandgap capture and release the drifting carriers resulting in the increase of the transit time. Thereafter, the TOF transit times hold the information on the DOS inside the bandgap of a material. Measurements of the TOF transit times for amorphous and β-rhombohedral boron layers are reported in [9]. It is evident that the transit times are changing with the process conditions. Also, the transit times for β-rhombohedral boron are comparable to the values for amorphous boron. Similarities in the electrical and structural characteristics justify later use of DOS of β-rhombohedral boron as a model of the DOS of amorphous boron.

III. Simulations and Results

Influence of the amorphous boron properties on the *pnp* bipolar transistor electrical characteristics is investigated by embedding amorphous boron model in Sentaurus TCAD software from Synopsys [10]. Simulated emitter region consists of boron layer and bulk silicon doped with boron as shown in Fig.1. For

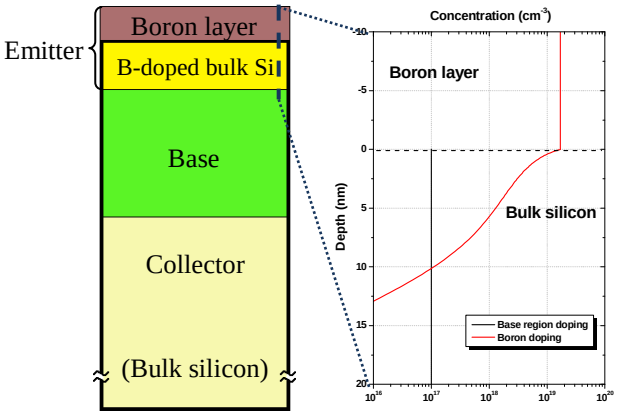

Figure 1. Cross section and doping profile of simulated *pnp* transistor structure with doping concentration and boron layer thickness corresponding to 30 min B_2H_6 exposure

comparison, two different structures have been analyzed. The top boron layer is assumed to have physical properties of:

a) c-Si doped with boron (B-doped silicon layer) and
b) amorphous boron (amorphous boron layer).

B-doped silicon layer has exactly the same physical properties as the c-Si. Physical properties of the amorphous boron layer are the same as for c-Si with the exception of bandgap and the presence of trap states in the bandgap.

Thickness of the boron layer used in the simulations is a function of B_2H_6 exposure times [1] and varies between 0.6 and 10 nm. Bulk silicon is doped from the boron layer and the doping profile is obtained by the simulations of the diffusion process. Since the amorphous layer is an abundant source of boron, simulations of the constant-source diffusion are performed. The temperature of the diffusion is 700°C and the diffusion times are equal to the B_2H_6 exposure times. Doping profiles for the base and collector regions are chosen according to the process conditions reported in [5]. Doping of the base region is assumed to be 10^{17} cm^{-3} to achieve a noncritical width of the base region with a base Gummel number of 10^{11} – 10^{12} scm^{-4}. Doping profile of the simulated *pnp* transistor structure with doping concentration and boron layer thickness corresponding to B_2H_6 exposure time of 30 min is depicted in Fig. 1.

A. Simulations of Base Current

First, the base current of *pnp* transistor structures is simulated and extracted. Ideal base current is equal to the sum of the electron emitter current and the recombination current. Simulations are made for structures where the emitter region consists of:

a) only bulk silicon doped with boron (no boron layer),
b) B-doped silicon layer + bulk silicon doped with boron and
c) amorphous boron layer + bulk silicon doped with boron.

In all three cases the emitter region consists of bulk silicon doped with boron while the physical and geometrical properties of the top boron layer are changed

– no boron layer, B-doped silicon layer and amorphous boron layer. For the latest, the physical properties such as bandgap and trap states in the bandgap are varied.

Base currents for the *pnp* bipolar transistors with boron layer thickness of 10 nm and the bulk doping profile corresponding to B_2H_6 exposure time of 30 min are shown in Fig. 2. Simulations are done without the model for SRH recombination. From the simulation results it is evident that the boron layer and the physical properties of the layer have significant impact on the base current. For the structure with B-doped silicon layer in the emitter region, the base current is reduced compared to the structure with the bulk silicon doped with B in the emitter. Base current is reduced due to the increase of the total emitter region width and the corresponding increase of G_E. Wider bandgap of the amorphous boron layer, on the other hand, suppresses electron injection resulting in even lower base current compared to the base current of the structure with the B-doped silicon layer. In both cases the boron layer is doped with the same B concentration of $1.7 \cdot 10^{19}$ cm^{-3}. Blocking mechanism that leads to suppression of the electron current is examined further by the band diagram shown in Fig. 3. Here, the band diagrams for the structures with B-doped silicon layer and amorphous boron layer with bandgaps of 1.4 and 1.6 eV are plotted. For a wider bandgap of the amorphous boron layer, the energy difference between the conduction band of the *p*-region and conduction band of the *n*-region is increasing. Thereafter, the majority electrons from *n*-region see a larger potential barrier. Consequently, at the same bias point the injection of the electrons from the base to the emitter region is reduced resulting in smaller base current.

As seen in Fig. 2, the base current of the structure with trap states in the bandgap of the amorphous boron layer in the emitter region is higher than the base current of the structure with no boron layer. At steady state conditions the trap states in the bandgap are either filled or empty depending on the type of the traps and the Fermi energy. Filled trap states reduce the total concentration of carriers which affects the base current through the change in the minority carrier concentration. Charged traps also

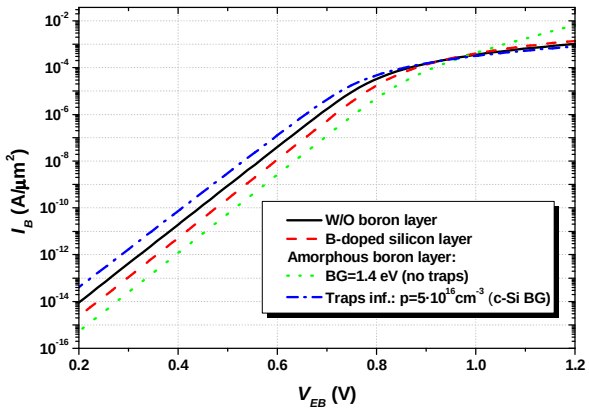

Figure 2. Base currents of *pnp* bipolar transitors with different emitter region configurations. Doping concentration and boron layer thickness correspond to 30 min B_2H_6 exposure.

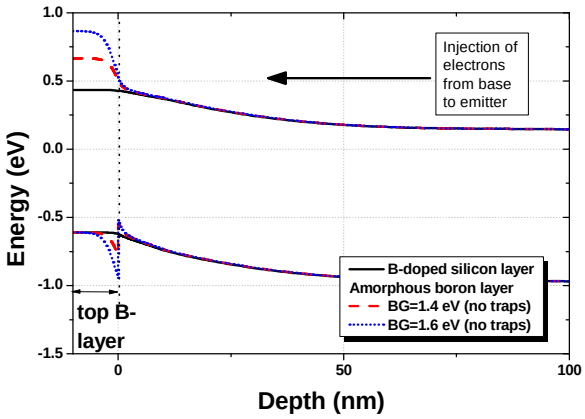

Figure 3. Band diagram of structures with B-doped silicon layer and amorphous boron layer with different bandgaps. Layer thickness and bulk silicon doping correspond to 30 min B_2H_6 exposure. V_{EB} = 0.6 V.

act like scattering centers thereafter influencing the carrier mobility. Simulations are made for structures where the trap concentration in the amorphous boron layer is varied to obtain majority carrier concentrations of $1.7 \cdot 10^{19}$ (no traps), $5 \cdot 10^{18}$, $5 \cdot 10^{16}$ and 10^{15} cm^{-3}. Here, the bandgap is kept constant and the same as for the bulk silicon. Band diagrams of structures with B-doped silicon layer and amorphous boron layer with different trap concentrations in the bandgap are shown in Fig. 4. Reduced majority carrier concentrations, compared to the majority concentration of B-doped silicon layer without traps in the bandgap, change the quasi-Fermi level in the amorphous boron layer and the level moves toward the middle of the bandgap. Thereafter, the valence and conduction bands of the amorphous boron layer decrease with respect to the valence and conduction bands of the c-Si at the α-B/silicon interface. The decrease of the valence band of the amorphous boron layer causes the potential barrier to decrease leading to the increase of the electron injection from the base region which, consequently, increases the base current.

Minority carrier concentrations of the *pnp* bipolar transistors with boron layer thickness and the bulk doping profile corresponding to B_2H_6 exposure time of 30 min

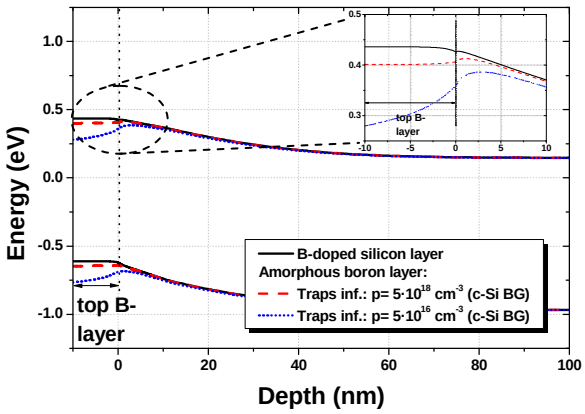

Figure 4. Band diagram of structures with B-doped silicon layer and amorphous boron layer with different trap concentrations in the band-gap.Bandgap of α-B layer is the same as for c-Si. Layer thickness and bulk silicon doping correspond to 30 min B_2H_6 exposure. V_{EB} = 0.6 V.

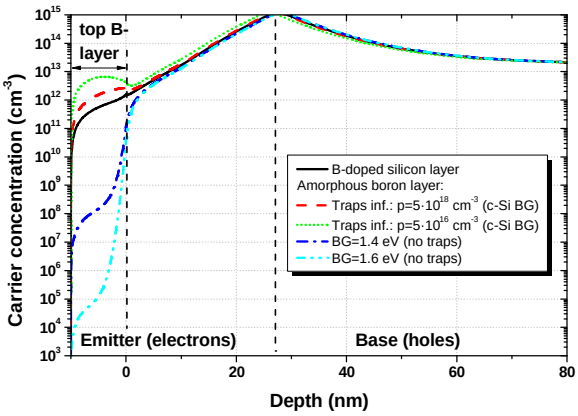

Figure 5. Minority carrier concentrations in the base and the emitter region. Trap concentrations and the bandgap of the amorphous boron layer are varied. Bulk doping and boron layer thickness correspond to 30 min B_2H_6 exposure. V_{EB} = 0.6 V.

are shown in Fig. 5. Significant difference between the minority carrier distribution curves for simulated structures can be observed in the boron layer. For B-doped silicon layer and amorphous boron layer with wider bandgaps and different trap concentrations in the bandgap the carrier distributions and the concentration gradients in the bulk silicon are the same. Influence of trap concentration on the mobility is also included in the simulations by using the model for carrier mobility that is dependent on the doping and the trap states concentrations.

B. Simulations of Emitter Gummel Number

The emitter Gummel number is extracted from the simulations of the *pnp* bipolar transistors. The ideal electron current injected from the base to the emitter (base current) can be written as:

$$I_{nE} = \frac{qAn_{i0}^2}{G_E}\left(\exp\left(\frac{V_{EB}}{V_T}\right)-1\right), \qquad (3)$$

where A is the cross-section of the *pn*-junction, V_{EB} is the voltage across the emitter-base *pn*-junction and V_T is the thermal voltage.

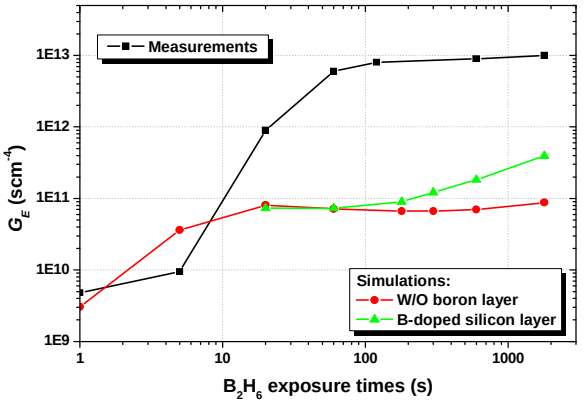

Figure 6. Comparison of measured and simulated G_E for different B_2H_6 exposure times. Simulations refer to transistors with no boron layer and B-doped silicon layer in the emitter region.

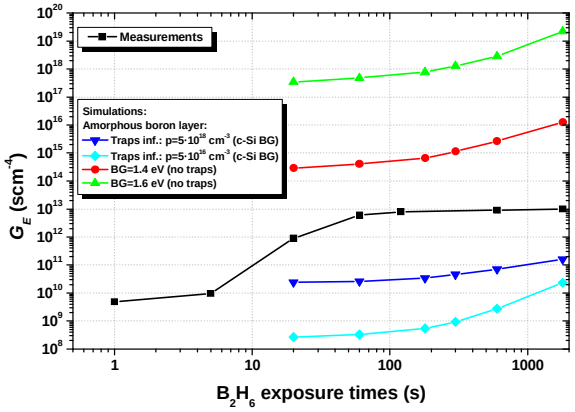

Figure 7. Influence of the bandgap and the trap states in the bandgap of amorphous boron layer on G_E for various B_2H_6 exposure times.

The measured G_E from [5] is compared to the simulated G_E of the *pnp* bipolar transistors for three cases of the top layer of the emitter region described in the previous section – no boron layer, B-doped silicon layer and amorphous boron layer. Bulk boron doping and the thickness of the boron layer are defined by B_2H_6 exposure times. Comparison of the measured G_E and simulated G_E for the structures with no boron layer and B-doped silicon layer in the emitter region is shown in Fig. 6. Simulations result in up to two orders of magnitude lower G_E for the cases of emitter region with no boron layer and B-doped silicon layer compared to measured G_E. It can be concluded that the physical properties of B-doped silicon layer are not appropriate for the modeling of the high G_E reported in the measurements.

The measured G_E is also compared to the simulated G_E of the *pnp* bipolar transistors with amorphous boron layer in the emitter region. Influence of the bandgap and the trap states of the amorphous boron layer on G_E is analyzed separately and shown in Fig. 7. Simulations show that G_E for the analyzed bandgaps of 1.3 to 1.7 eV of amorphous boron layer is more than 2 decades larger than the measured G_E. On the other hand, simulated G_E for amorphous boron layer with trap states is more than 2 decades smaller than the measured values. This leads to conclusion that the bandgap and the traps states must be used in conjunction to define the amorphous boron layer properties that lead to high G_E.

As in Section II, DOS of amorphous boron has not yet been reported. Due to some similarities with amorphous boron, DOS of crystalline β-rhombohedral boron is used to model the combined influence of the trap states and the bandgap of the amorphous boron layer. DOS of β-rhombohedral boron is based on the material data by Hoard et al. [11] and Slack et al. [12]. Electronic structure calculations for the aforementioned data were done using the band calculation program CASTEP and the results are reported in [13]. DOS of amorphous boron layer used in the simulations are approximations of these calculated DOS. Comparison of calculated DOS and the model used in the simulations is depicted in Fig. 8. Model of the DOS is approximated as the sum of exponential tails of the conduction and valence bands and one or two Gasussian distributions representing dangling bond states. For the proposed DOS, TOF simulations are made. Results of the

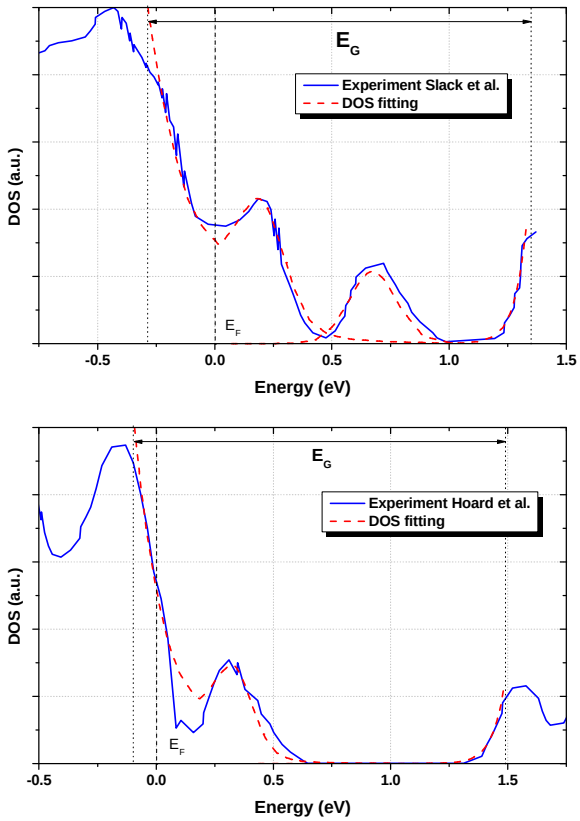

Figure 8. DOS for β-rhombohedral boron based on the structural data by Slack et al. and Hoard et al. and the fitted DOS used as the model of DOS of amorphous boron.

simulations are compared to the TOF measurements reported in [9] and given in Table 1. Simulated drift time for amorphous boron with DOS based on the structural data by Slack et al. agrees with the measured values for β-rhombohedral boron and amorphous boron. For the amorphous boron with DOS based on the structural data by Hoard et al. the transit time is more than 3 orders of magnitude smaller than the measured values.

G_E is simulated using the proposed DOS and the results are depicted in Fig. 9. Simulations of G_E for structures with amorphous boron layer where the layer has DOS of β-rhombohedral boron based on structural data by Slack et al. show good agreement with the measured values in the range of 1 to 10 minutes of B_2H_6 exposure times. For the simulations with amorphous boron layer with DOS based on Hoard et al.'s structural data, G_E is more than 3 orders of magnitude higher than

TABLE I. COMPARISON OF MEASURED AND SIMULATED TOF TRANIST TIMES

Simulations: amorphous boron with **Slack et al. DOS**	10^{-7}
Simulations: amorphous boron with **Hoard et al. DOS**	$1.3 \cdot 10^{-10}$

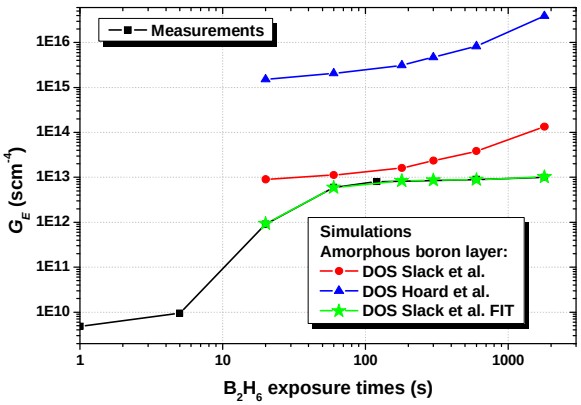

Figure 9. Combined influence of bandgap and trap states in the bandgap on G_E for various B_2H_6 exposure times.

the measured values. Bandgap of the amorphous boron layer in both cases is similar, i.e. 1.62 eV and 1.58 eV for the DOS based on structural data of Slack et al. and Hoard et al., respectively. Significant difference between two simulation results is caused by the effect of trap states. The trap states reduce the majority carrier concentration from $9 \cdot 10^{17}$ cm^{-3} in the amorphous boron layer with Hoard et al.'s DOS to $5 \cdot 10^{14}$ cm^{-3} in the amorphous boron layer with Slack et al.'s DOS.

Fitting to the measured G_E could be done by changing the bandgap or the trap concentration in the amorphous boron layer. Fitting is done for the amorphous boron layer with Slack et al.'s DOS. If the trap concentration in the bandgap is changed, there will be a significant difference between the simulated and measured t_T. Meanwhile, if only the bandgap of the boron layer is reduced, simulated drift times remain unchanged. The bandgap of a thin amorphous layer decreases with increasing film thickness [14]. Since the thickness of the amorphous boron layer is increasing with B_2H_6 exposure time, the fitting is achieved by decreasing the bandgap of the amorphous boron layer. Fitted G_E is given in Fig. 9 showing excellent agreement with the measured data.

IV. CONLUSION

In PureB diodes the physical properties of the amorphous boron layer play an important role on the electrical properties of bipolar *pnp* transistors with an amorphous boron layer emitter. In the presented modeling, a wider bandgap of the amorphous boron layer as compared to that of the bulk silicon is assumed, thus resulting in the formation of heterostructure. Also, the trap states in the bandgap are assumed and they will change the carrier concentration and mobility. A wider bandgap of the amorphous boron layer is shown to suppress the injection of electrons resulting in the decrease of the base current and consequently in the increase of G_E. At the same time, the traps would reduce the carrier concentration and increase the base current decreasing the G_E. From the applied DOS of β-rhombohedral boron as a model of the DOS of the amorphous boron layer it has been observed that the combined influence of the wider bandgap and the presence of trap states in the bandgap could explain the high emitter Gummel number.

vladimir.tudic@vuka.hr

Abstract - Photovoltaic properties of nanocrystalline (nc-Si:H) heterojunction thin film solar cells with the single junction structure of TCO/p- nc-Si:H/i1- nc-Si:H/i2- a-Si:H/n- nc-Si:H/AZO was studied by a computer modeling software AMPS-1D in this paper. Due to spectral response of solar cells with the examined nc-Si thin films as active elements showed a narrower spectral distribution and a blue shift comparing to pure amorphous solar cells. The results were higher efficiency than amorphous cells due to higher optical gap (higher output voltage) and better fill factor (higher mobility).

I. INTRODUCTION

The electrical properties of amorphous-nano-crystalline thin films deposited by Plasma Enhanced Chemical Vapor Deposition (PECVD) were studied by a computer modeling software One-dimensional Analysis of Microelectronic and Photonic Structures (AMPS-1D) in this paper. The possibility of using hydrogenated amorphous-nano-crystalline silicon (nc-Si:H) thin film solar cells in the production of third generation photovoltaic [1] is most standing challenge. Nano-crystalline thin films are one of the most promising concepts in new thin film solar cells technology [2]. First benefit of nano-crystalline thin film layers are higher value of energy gap in correlation with the size distribution of individual crystal sizes and the crystalline to amorphous fraction [3]. The nano-crystals remain as individual in amorphous matrix (Fig.1) enabling quantum size effects related to small dimensions of crystals. Measurements of the optical properties showed that the spectral distribution of the absorption coefficient in a whole range of crystal to amorphous fractions remained close to pure amorphous silicon in the visible part of the spectrum and showed square dependence on the photon energy (Tauc gap) [4]. The average optical gap was larger for smaller nano-crystals and a higher crystal fraction just confirming the quantum size effects that correspond to quantum dots [5]. The second benefit for using nano-crystalline thin film layers in standard p-i-n solar cell structures is low degradation of electrical properties. Crystal grains either uniform across the sample or slightly larger when located closer to the surface some hove increases material stability to light iluminance degradation process.

A possible application of (nc-Si:H) film as active part in solar cells in a typical p-i-n solar cell structure was tested by computer simulator in respect to overall performance.

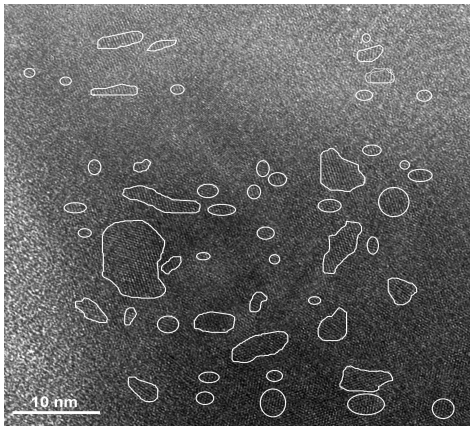

Figure 1. Typical HRTEM micrograph of amorphous-nano-crystalline silicon (nc-Si:H) thin film; 30 vol.% crystalline fraction, published in [4].

II. NANO-CRYSTALLINE LAYER

Nano-crystalline silicon (nc-Si) films consist of a matrix of amorphous silicon (a-Si) with embedded silicon crystals of nanometric dimensions [6, 7]. This material has improved properties with respect to pure amorphous Si and bulk crystalline Si (c-Si) owning quantum confinement effect [8]. When compared to amorphous silicon, nc-Si has better electrical transport characteristic [9], possibility to tailor the optical band gap [10, 11] and resistance to light induced degradation [12]. The main advantage in comparison with crystalline silicon is its higher absorption, which allows efficient solar cells in thin film designed device. This material could be fraction of 'small crystals', expected to show effect of increase in optical gap due to quantum confinement predictable according to effective mass theory or quantum dots.

The optical properties of nc-Si thin films strongly depend on the production conditions and determination of the structural properties of the thin film.

The spectra of absorption coefficient, $\alpha(E)$, of typical nc-Si thin film calculated from transmittance by Fourier transform photocurrent spectroscopy (FTPS) and photo deflection spectroscopy (PDS) is shown in Figure 2.

Absorption coefficient data we used in our calculation and device simulation was published in literature [6, 13]. Amongst others, sample number two (K2) is chosen because of convenient value of its band gap energy (E_g=1.95eV) caused by lower crystalline fraction (vol. 30%).

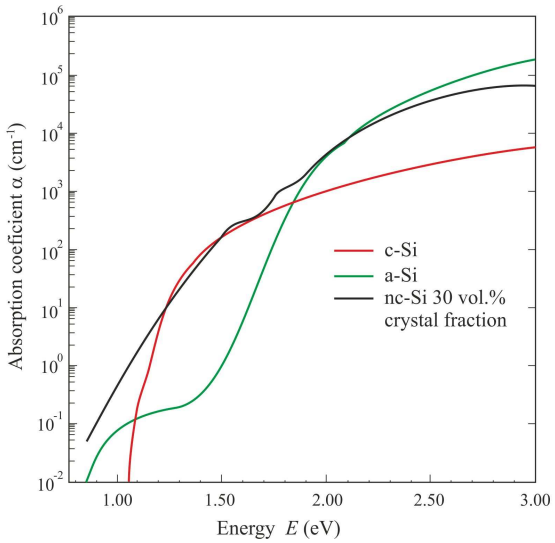

Figure 2. Distribution of absorption coefficient of nc-Si (black line), amorphous Si (green line) and mono-crystal Si (red line) calculated from FTPS and PDS.

III. SIMULATION MODEL

Computer modeling software AMPS-1D can simulate all modeled semiconductor and photovoltaic device structures. In the present version of AMPS-1D user can chose one of two different calculation models: Density of States (DOS approach) and Carrier Lifetime Model (CLM). DOS approach is more suited for silicon amorphous and nano-crystalline thin films layers due to large defect densities in midgap states [14, 15].

Model of photovoltaic device can be simulated throe optical and material parameters on device designed structure. Material and optical properties affect electrical parameters in tree differential equations in correlation: the Poisson's equation, electron continuity equation and hole continuity equation. Those tree equations are solved simultaneously under non-equilibrium steady-state conditions (i.e., under the effect of light, voltage bias or both) by using method of finite differences and Newton-Raphson technique. The used equations are:

Poisson's equation,

$$\frac{\rho(x)}{\varepsilon} = \frac{\partial \Psi(x)}{\partial x} \tag{1}$$

electron continuity equation,

$$\frac{1}{q}\frac{\partial J_n(x)}{\partial x} = R(p(x), n(x)) - G_{op}(x) \tag{2}$$

and hole continuity equation,

$$\frac{1}{q}\frac{\partial J_p(x)}{\partial x} = G_{op}(x) - R(p(x), n(x)). \tag{3}$$

All carriers in semiconductor layer can be described by net charge density value $\rho(x)$, expressed like

$$\rho(x) = q[p(x) - n(x) + p_T(x) - n_T(x) + N_A - N_D] \tag{4}$$

and the present electrostatic field E is defined as

$$E = \frac{\partial \Psi(x)}{\partial x}. \tag{5}$$

In equation ε is the dielectric constant, E is electrostatic field, $\Psi(x)$ represents the position of energy in the local vacuum level, x is position in the device, n and p the extended states density in conduction and valence band, respectively, p_T and n_T the trapped hole and electron population density, N_A acceptor doping density, N_D the donor doping density, if exists, the q the electron charge, $R(x)$ the recombination rate, $G_{op}(x)$ the optical generation rate of free electron-hole pair, J_n and J_p the electron and hole current density, respectively. The term $R(x)$ is the net recombination rate resulting from band-to-band (BTB) direct recombination and Shockley-Read-Hall (SRH) indirect recombination traffic through gap states. The model used in AMPS for indirect recombination assumes that the traffic back and forth between the delocalized bands and the various types of delocalized gap states is controlled by SRH, capture and emission mechanisms. Since AMPS has the flexibility to analyze device structures which are under light bias (illumination) as well as voltage bias, the continuity equations include the term $G_{op}(x)$ which is the optical generation rate as a function of x due to externally imposed illumination.

Generally, the three state variables completely define the state of a device: local vacuum energy level Ψ and the quazi-Fermi levels E_{Fp} and E_{Fn}. Once those tree dependent variables are calculated as a function of position in device, all other parameter can be determinate as its function. In thermodynamic equilibrium, the Fermi level is a constant as a function of position and hence the tree equations (1-3) essentially reduce to Poisson's equation. Therefore, local vacuum energy level Ψ is the only variable to solve in thermodynamic equilibrium.

Otherwise, in non-thermodynamic equilibrium steady-state, a system of three correlated non-linear second order differential equations in the tree unknowns (Ψ, E_{Fp}, E_{Fn}) is obtained. Further calculation need six boundary conditions, two for each dependent variable. The first two boundary conditions are modified versions of the ones used for solving Poisson's equation in thermodynamic equilibrium:

$$\Psi(0) = 0 - \chi(L) - \varphi_{bL} + \chi(0) - V \tag{6}$$

and

$$\Psi(L) = 0 \tag{7}$$

where L is the total length of the modeled device, $\chi(0)$, $\chi(L)$ are the electron affinities at x=0 and x=L, respectively and V is applied voltage. Zero value of local

vacuum energy level Ψ is at boundary point $x=L$. The four other boundary conditions are obtained from imposing constraints on the currents at the boundaries at $x=0$ and $x=L$. These constraints force the mathematics to acknowledge the fact that the currents must cross at $x=0$ and $x=L$ (contact position) by either thermionic emission or interface recombination. Mathematically expressed current values at boundaries:

$$J_n(0) = qS_{n0}[n(0) - n_0(0)] \quad (8)$$

$$J_p(0) = qS_{p0}[p(0) - p_0(0)] \quad (9)$$

$$J_n(L) = qS_{nL}[n(L) - n_0(L)] \quad (10)$$

$$J_p(0) = qS_{pL}[p(L) - p_0(L)] \quad (11)$$

where S_{n0}, S_{p0} are surface recombination velocities for electrons and holes respectively at the $x=0$ interface and the quantities are the corresponding velocities at the $x=L$ interface. Strongly limited by thermionic emission largest value of recombination velocities cannot over cross $10^7 cms^{-1}$. In equations (8-9) n(0) and p(0) are the electron and hole density at $x=0$, n(L) and p(L) are the same values at $x=L$. Analogy, $n_0(0)$ and $p_0(0)$, $n_0(L)$ and $p_0(L)$ are the electron and hole density at the thermodynamic equilibrium at boundaries $x=0$ and $x=L$, respectively. Now, when all conditions are defined, simultaneously calculation of Ψ, E_{Fp} and E_{Fn} can be obtained.

The model used in our simulation for gap states consist of two exponential tail states distributions and two Gaussian distributions of deep defects states (Fig.3).

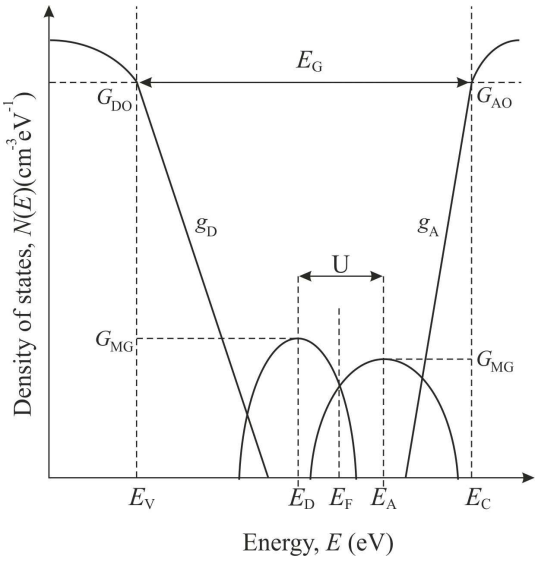

Figure 3. Density of stated distribution where G_{DO} / G_{AO} are exponential prefactors of the donor-like / acceptor-like tail states at the extended band edges, g_D / g_A are the donor-like / acceptor-like Urbach tail states, G_{MG} is constant density mid-gap value, E_D / E_A are Gaussian donor-like/acceptor-like characteristic energy density, U is correlation energy, E_V / E_C are valence / conduction band energy level, E_F is level of Fermi energy.

IV. SOLAR CELL STRUCTURE

In this paper we have simulated two types of single junction solar cells, the first type have the standard structure: p- a-SiC:H/i- a-Si:H/n- a-Si:H and the second type have the following structure: p- nc-Si:H/i1- nc-Si:H/i2- a-Si:H/n- nc-Si:H (Fig.4). Thickness of layers for the first structure is as follows: p- 8 nm/i- 350 nm/n- 15 nm and for second extended structure: p- 8 nm/i1- 50 nm/i2- 300 nm/n- 15 nm. Output parameters result in both modeled cases (absorber i- and absorbers i1-/i2-) of total thickness 350 nm must be comparable.

We propose an implementation of chemically textured zinc-oxide ZnO:Al film or SnO_2 as a front TCO in our p-i-n solar cells, and in combination with Ag as a textured back reflector-enhancing dielectric layer for additional efficiency. Such modeled cells exhibit excellent optical and light-trapping properties demonstrated by high short-circuit current densities.

A. Boundary conditions

The tree governing equations (1), (2) and (3) must hold every position in the device and the solution to those equations involves determining the state variables $\Psi(x)$ $E_{Fp}(x)$ and $E_{Fn}(x)$. Non-linear and coupled equations cannot be solved analytically, numerical methods must be utilized. Boundary conditions must be imposed on the sets of equations. These are expressed in terms of conditions on the local vacuum level and the currents at the contacts. To be specific the solution to equations (1), (2) and (3) must satisfy the boundary conditions (6-11).

In computer modeling program AMPS $\Psi(0)$ is PHIB0, $\Psi(L)$ is PHIBL, S is recombination speed for holes and electrons depending on carrier position. Parameter RF is reflection coefficient at $x=0$, RB is reflection coefficient at $x=L$. In actual situation RF is parameter of lost photon flux transmitting throe glass substrate and TCO layer. Measurements of solar cells internal optical loses (in visible spectrum) showing wavelength (λ) or energy dependence [6, 11, 19]. Reflection coefficient RB depends of optical characteristics of back electrode which acts as an optical mirror and efficient light trapping. We propose a reflection-enhancing dielectric layer such as Al-doped zinc oxide (AZO) between the silicon and the metal. The properties of the front contact and back contact used as the model parameters are shown in Table I.

Table I. Boundary conditions in AMPS: PHIBO is $\Psi(0)$ at $x=0$; PHIBL is $\Psi(L)$ at $x=L$ (total device length); SNO-SNL-SPO-SPL are surface recombination speeds at $x=0$ and $x=L$ (N=electron, P=hole); RF is reflection coefficient at $x=0$; RB is reflection coefficient at $x=L$.

Front Contact	Back Contact
PHIBO = 1.730 eV	PHIBL = 0.120 eV
SNO = $1x10^7$ cm/s	SNL = $1x10^7$ cm/s
SPO = $1x10^7$ cm/s	SPL = $1x10^7$ cm/s
RF = 0.250	RB = 0.600

B. Solar cells parameters

The input parameters of modeled device layers that simulate output characteristics of actual solar cell are given in Table II. Published selected mobility parameters are taken from references [17, 18]. For calculation of solar cell output it was used the standard global illumination conditions, air-mass 1/cosΘ (AM1.5 spectrum), 1000 W/m^2 and 300 K temperature.

In nano-crystalline thin film layers transport mechanism strongly depends of carrier mobility μ (cm^2 V^{-1}s^{-1}). Electron μ_n and hole μ_p mobility have dependence to crystal lattice temperature also donor-like and acceptor-like doped concentrations, suggesting its maximal values in bulk material. Fraction of 'small crystals' in nano-crystalline material, expected to show effect of increase in optical gap due to quantum confinement predictable according to effective quantum dots and significant enhancing of mobility up to two order of magnitude. For example, electron mobility at temperature of 300K in bulk (intrinsic) crystalline silicon has mobility value 20-40 cm^{2}V^{-1}s^{-1}. In nano-crystalline thin film electron mobility in bulk can reach up to 2000 cm^{2}V^{-1}s^{-1}. According to doping level in silicon thin film mobility of carriers decreases rapidly [18].

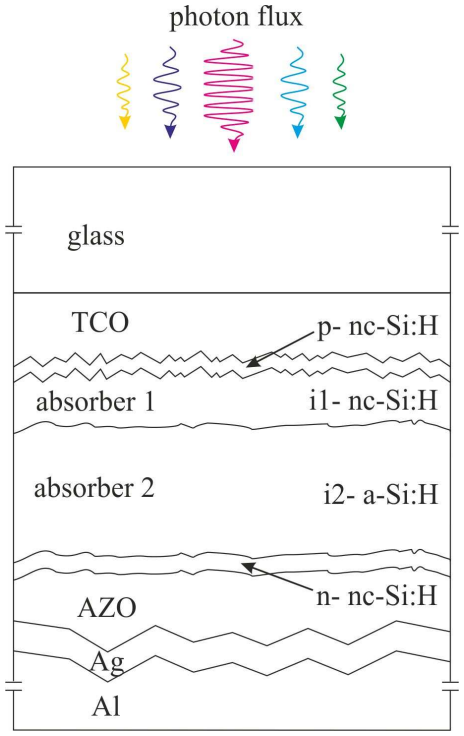

Figure 4. Extended model of solar cell with two absorbers: foton flux enters glass substrate (2-3 mm), Transparent Conductive Oxide (TCO) is solar cell front contact for collecting holes (0.3 μm), nano-crystalline p- window layer (8 nm), nano-crystalline top absorber i1- (50 nm), amorphous base absorber i2- (300 nm), nano-crystalline n- back layer (15 nm), Aluminum-doped Zinc Oxide (AZO) is reflection-enhancing dielectric layer (0.1 μm), Ag as a textured back reflector (0.5-2 μm), Aluminum back contact electrode (2-3 mm).

Table II. Material parameters written in AMPS used to simulate the output characteristic of the modeled single junction solar cell.

Layer Parameters	Solar cell layers

V SIMULATION RESULTS AND DISCUSION

The performance of modeled solar cells was designed and analyzed in respect to the open circuit voltage (V_{oc}), short circuit current density (J_{sc}), fill factor (FF) and efficiency (η) by incorporating the layer parameters into AMPS- 1D. In this study we simulated two types of single junction solar cells, the first type has the standard structure: p-i-n with amorphous absorber of

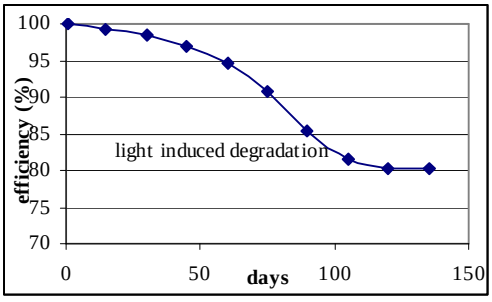
350 nm thickness and for second extended structure: p-i1-i2-n with top nano-crystalline absorber of 50 nm thicknesses and base amorphous absorber of 300 nm. In second extended simulated device both top p- and bottom n- layers are also nano-crystalline thin film layers. The absorption profiles data of nano-crystalline layer (sample K1-K4) was taken from references [4] and [6]. We have studied the effect of varying the mobility band gap (E_g) in samples and its implication to output solar cell characteristic. In standard AM1.5 illumination for the single p-i-n structure simulation results are: J_{SC}=8.211 mA, η=6.86 %, FF=0.828 and V_{OC}=1.109 V. Second extended single junction structure pointed out better output parameters: J_{SC}=8.444 mA, η=7.16 %, FF=0.839 and V_{OC}=1.011 V. For both type of devices simulation promotes the same electric field to ensure good collection of photo-generated electron-hole pairs in absorber structure. In second simulation improvement in efficiency is supported by higher mobility and therefore better fill factor as shown in Table III.

Table III. Modeled illuminated I-V characteristic of two types of single junction solar cells: p-i-n and p-i1-i2-n structure.

Solar cell type / Output parameters	p-i-n	p-i1-i2-n
J_{SC} (mA/cm^2)	8.211	8.444
η (%)	6.886	7.16
FF	0.828	0.839
V_{OC} (V)	1.009	1.011

First device structure only with amorphous layers has scattered crystal lattice order and therefore is not resistant to light induced degradation. Therefore, tree month after light exposure efficiency will be decreased by at least 20%. Light induced degradation of such solar cells has been simulated and results are shown in Table IV. Predictable calculations for solar cell with amorphous layers suggest efficiency of 5.5 % after degradation period.

Table IV. Light induced degradation simulation of solar cell with amorphous layers. Efficiency value after degradation period is lowered to the 80% of the initial value.



VI CONCLUSION

In this study we have simulated two types of single junction solar cells with nano-crystalline and amorphous absorbers using simulation computer program AMPS-1D. A series of simulations were carried out in order to calculate the efficiency of modeled solar cell by varying the properties each of layers in the range published in the literature. The obtained results show clearly that the nano-crystalline silicon thin film is a very interesting material to be used in single junction solar cells and tandem cells, respectively.

The substitutions of the amorphous p- window layer and n- layer in second type cell by a nano-crystalline silicon thin film layer leads to improvement of the output cells parameters: short circuit current incensement from 8.211 mA/cm^2 to 8.444 mA/cm^2 and efficiency enhancement from 6.886 % to 7.16 %. The additional improvement with i1- nano-crystalline top absorber is due to higher mobility of free carriers in all nano-crystalline layers, especially in additional absorber layer.

Nano-crystalline thin film solar cell model perform better cell efficiency and that is in good agreement with experimental results reported in the literature.

Abstract — Liquid Crystal Thermography (LCT) is commonly used for hotspot identification and peak-temperature measurement in electronic devices. We use LCT to characterize GaN/Si and GaN/SiC high-electron mobility transistors and extract the thermal boundary resistance between the GaN epilayers and the substrate on these transistors.

I. INTRODUCTION

Thermal resistance is an important factor in specifying the power capability of power electronic devices. Besides the commercial need, the measurement of thermal performance of electronic devices is used to extract thermal parameters in device structures, especially when one is interested in estimating thermal properties of structures within a device that are not a priori known. Recently, thermal boundary resistance (TBR) between GaN epilayers and the substrate have attracted attention due to its dependence on growth conditions, epilayer structure, and manufacturer [1], [2], [3], [4]. A number of techniques have been demonstrated to evaluate the TBR [2], [4]. In this work, we use Liquid Crystal Thermography (LCT) to characterize thermal crosstalk between two low-frequency AlGaN/GaN high-electron mobility transistors (HEMT) adjacent on a single chip and use this information to determine thermal boundary resistance between the GaN epilayers and the substrate for two different substrates commonly used for GaN growth: silicon and silicon carbide.

Liquid Crystal Thermography is one of many techniques for estimating thermal resistance and identifying hotspots on semiconductor devices and, in particular, high power field-effect transistors [5], [6], [7]. We combine thermal resistance and thermal crosstalk measurements with heat-flow modeling and use unknown structure parameters as free parameters to fit a model to the measured values of thermal resistance and thermal crosstalk. A sensitivity analysis of the fitting parameters is included indicating the limits of accuracy of the presented method in estimating thermal boundary resistance between the GaN epilayers and the substrate.

II. DEVICE STRUCTURES, FABRICATION DETAILS

We study HEMTs built on two different layer structures and substrates shown in **Figure 1**. The wafers were purchased from commercial vendors of GaN/substrates. The device layout is tailored for DC testing or possibly low-frequency RF (~1GHz) with the primary purpose in evaluating the epilayer quality. High-electron mobility transistors with two gate-fingers and no air-bridges are processed using a four-mask process. The device physical dimensions were W = 2 x 200 µm, L_G = 2 µm, L_{GD} = 4 µm, gate pitch 35 and 39 µm (shown in photo in **Figure 2**). The barrier thicknesses range between 10 and 20 nm and hence they negligibly contribute to the overall thermal resistance. For modeling purposes, the heat source is assumed to be an infinitely thin rectangle located at the two-dimensional electron gas with sides equal to 200 × 3 µm². We are interested in characterizing the resistance to heat flow presented by the layer structure appearing between the GaN epilayers and the substrate. The thermal boundary resistance of those layers is uncertain and can not be accurately estimated a priori as the dislocation density profile in the transition layers, which significantly contributes to the thermal resistance of those layers, is not known and there is no knowledge how the dislocation density correlates with the thermal conductivity in AlGaN materials. For these reasons, we look at the entire GaN-to-substrate layer structure as one thermal boundary to be characterized.

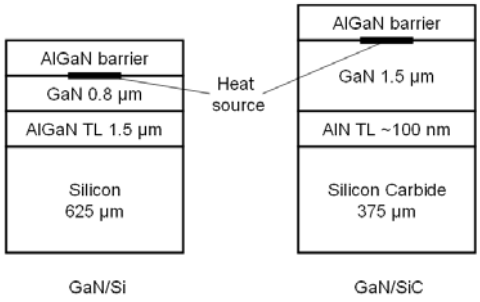

Fig. 1 – GaN/Si and GaN/SiC HEMT structures. Only physical parameters relevant for thermal modeling in this work are shown.

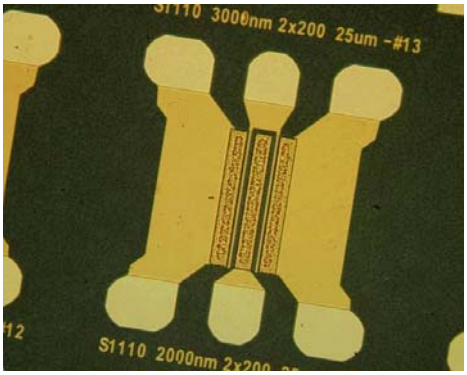

Fig. 2 – Top view if a completed HEMT

The devices were DC characterized, diced into multi-transistor chips (6 HEMTs each chip) shown in **Figure 3**, attached into standard packages [8], and wire-bonded. For thermal resistance measurement, we need only to apply a controlled amount of DC power to the HEMT. Four of the

six HEMTs were wire-bonded with their gates shorted to source/ground. In this way, power to each HEMT can be delivered by selecting a single wire to the package. Furthermore, shorting the gate to the source at the chip (using a very short bondwire) eliminated the need for transistor stabilization. For thermal resistance measurement the package is bolted to a nickel-plated copper heat spreader as shown in **Figure 4**. The five wires leading to the package are the four drains and one lead to the ground (source and gate). The last wire is the thermocouple located inside the heat-spreader below the package.

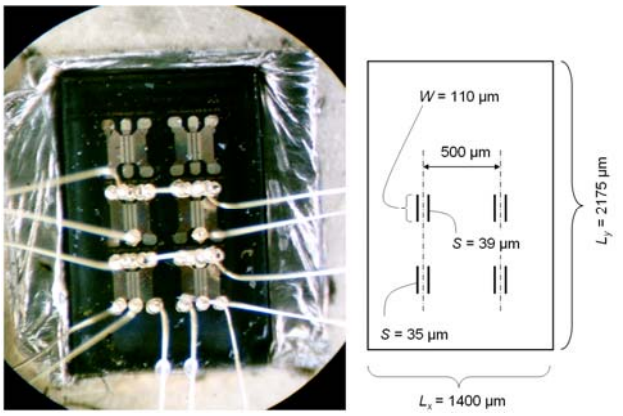

Fig. 3 – Multi-HEMT chip with dimensions

III. LIQUID CRYSTAL THERMOGRAPHY

Our LCT measurement is based on using nematic liquid crystals which change crystalline order from the nematic phase into isotropic phase at a known temperature T_{LC}. These are also known as *nematogens* in which the optical state changes with temperature (rather than electric field). For this measurement, a several-micrometer thick layer of liquid crystal is disposed over a transistor and illuminated with polarized light, while the reflected light is viewed through another polarizer. When the crystal temperature is below T_{LC}, incident polarized light remains polarized upon reflection, but above T_{LC} the reflected light is depolarized. This property is then used to optically determine when a certain area of liquid crystal is above or below the T_{LC} visually using a microscope. One obtains the thermal resistance Θ_{TH} by measuring the power P delivered to the device when the channel of the transistor reaches T_{LC} and the heat-sink temperature T_{HS} using

$$\Theta_{TH} = (T_{LC} - T_{HS})/P. \quad (1)$$

The experimental setup is illustrated in **Figure 5**. It consists of a trinocular microscope with a polarized white-light illuminator and an analyzer in the path of the light entering the microscope. A *J*-type thermocouple was embedded inside a nickel-plated copper heat-block about 0.5 mm below its surface. The heat block was placed on a temperature-controlled hot plate. In many reported LCT measurements, a single reading of P and T_{HS}, is taken and then equation (1) is used to determine thermal resistance. We improve the measurement accuracy by making multiple measurements of power P for a sequence of heatsink temperatures T_{HS} and determine the thermal resistance from the slope $\Theta_{TH} = -\,\mathrm{d}T_{HS}/\mathrm{d}P$. In this way, we have (a) the ability to check whether the thermal resistance is indeed a linear function of the heatsink temperature, (b) improve the accuracy of the thermal resistance estimate by using linear regression of the data, and, most importantly, (c) obtain thermal-resistance values without knowing the exact value of T_{LC}. This latter fact is advantageous because the transition temperature and the temperature broadness of the nematic-isotropic transition can be altered by the presence of water or remaining solvent in the crystal.

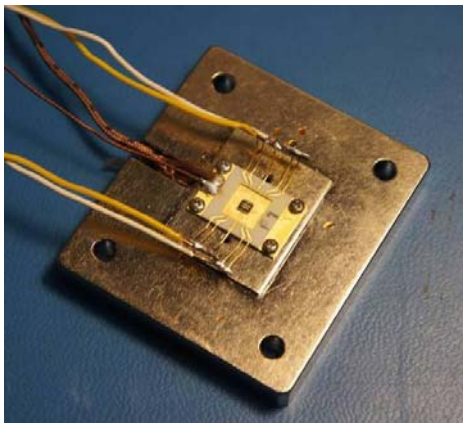

Fig. 4 – Packaged multi-transistor chip attached to a heat-block and wired.

There is a variety of nematic liquid crystals that can be used for LCT measurements [6] although manufacturers most often do not advertise them for LCT applications. The suitability of a particular crystal depends primarily on the N-I transition temperature T_{LC}, which one would prefer to equal to the maximum device operating temperature. For AlGaN/GaN HEMTs the operating temperature is most often 150°C. In this way, one accounts for the effect of temperature-dependent thermal conductivity of the materials. However, the ability to easily dissolve the crystal, apply it and maintain it in a several-micrometer thick layer turns out to be more important. The melting temperature in nematic liquid crystals is below the N-I transition temperature so the crystal is liquid at the temperature where the measurement is made. This can present a difficulty with thin films if the crystal does not wet the underlying surface well. This problem varies from crystal to crystal and greatly depends on the shape and the chemistry of the underlying surface. When starting with no background knowledge, one has to experimentally determine the suitability of a particular crystal to a device.

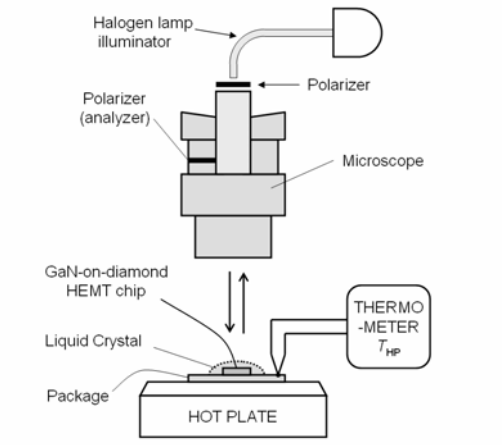

Fig. 5 Liquid Crystal Thermography setup

Organic solvents, such as, acetone [5] or chloroform (in this work) will dissolve most nematogens. The solution ratio is commonly 1:10 by volume and a single drop of this solution placed onto the die will provide a several micrometer thick layer after the solvent evaporates. Applying the crystal in dissolved form can be used to produce several micrometer thick layers and this will lead to several-micrometer resolution. In this work, we were consistently able to detect when the area between the gate and the drain on our devices reaches T_{LC}, which means that we achieve better than 4 μm spatial resolution.

We experimented with two types of crystals: one with T_{LC} = 153°C [9] and other with T_{LC} = 136°C [10]. The 153°C nematogen was selected because its T_{LC} is very close to 150°C, but we experienced a number of difficulties with this crystal. It did not wet the silicon nitride surface well and tended to form droplets once melted, sometimes having to interrupt the measurements to ad more crystal. Furthermore, once close to the T_{LC} temperature, the evaporation rate of the 153°C nematogen became noticeable: the time one could stay at temperature and make measurements was reduced to less than 15 min. We attempted resolving these difficulties by using thicker layer of the crystal by applying the undissolved crystal directly to the chip and melting it. This however produced a different problem: the amount of crystal deposited was harder to control and the varying thickness of crystal resulted in loss of resolution. The 136°C liquid crystal wetted the surface significantly better, but still not sufficiently to consistently cover the entire device. However, the crystal consistently wetted the area between the gate and the drain enabling repeatable measurements over an extended period of time (hours).

Fig. 6 - Photograph of the transistor below (left) and above (right) the nematic-isotropic transition temperature T_{LC}. The transition is unambiguously detectable to the eye, although this is not clearly visible in this image because of the limited spatial and contrast resolution of the camera.

IV. Thermal Resistance Measurement

The electrical biasing diagram for the multi-transistor device is shown in **Figure 7**. We connect two adjacent transistors to the external circuitry at any given time. We are interested in monitoring the thermal resistance associated with temperatures T_P, T_E, T_C, and T_B, for each of the devices 1 and 2, and the thermal crosstalk between devices 1 and 2, i.e., the power to device 2 required to bring T_P of device 1 to T_{LC} while a preset power is delivered to device 1. **Figure 8** illustrates the location of the these temperature points.

The thermal resistance measurement consists of finding the power P that needs to be delivered to a device so that the temperature of a specific spot on the chip (T_P, T_C, T_E, T_B) reaches T_{LC}. We know when temperature $T_P = T_{LC}$ because when $T_P > T_{LC}$ the channel of the HEMT will turn dark under the microscope. For temperatures $T_P < T_{LC}$ the liquid crystal on top of the HEMT is clear and transparent. The thermal-resistance measurements then proceed as follows: We first heat the hotplate to just below T_{LC} and then turn it off. As the hotplate cools we alternatively measure P_1 and P_2 for devices 1 and 2 (only one powered at any time). This measurement leads to the thermal resistance Θ_P and Θ_C for each individual device. During another optional temperature scan we measure Θ_E and Θ_B. These latter measurements often proved to be damaging to the device as the applied voltage sometimes exceeded the breakdown voltage. For this reason, the measurements were done only on some of the devices. An example of raw data from these temperature ramps are shown in **Figure 9**. The slope of the curves gives the thermal resistance and the x-axis intercept is T_{LC}.

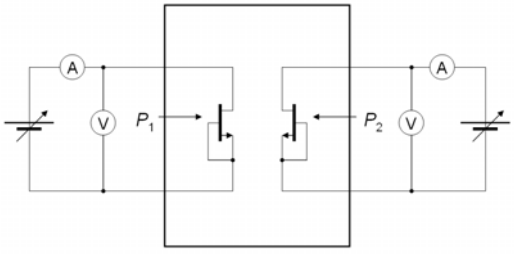

Fig. 7 – Electrical wiring of the devices

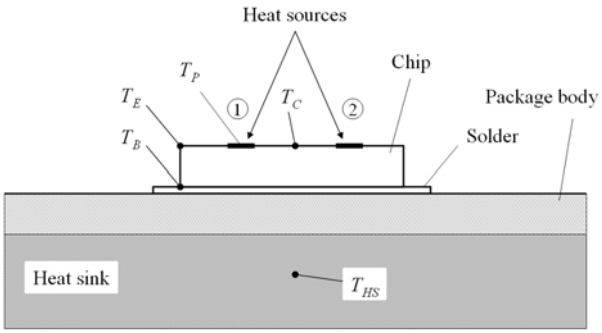

Fig. 8 – Location of temperature measurements.

The second measurement is done by setting the hotplate to a fixed temperature (between 120°C and 130°C) and then performing thermal crosstalk measurements. We make this measurement at a fixed temperature so that we can characterize the relationship between P_1 and P_2. This relationship was linear, as expected. We first find the power P_1 needed for device 1 to reach T_{LC}, then decrement P_1 somewhat and search for power P_2 which brings device 1 to T_{LC} again. We repeat the decrementing of P_1 until, if possible, we reach zero. We then repeat the same measurement on device 2. The raw data with the linear regression for such a measurement is shown in **Figure 10**.

We made measurements on four GaN/Si and ten GaN/SiC devices. The results are summarized in **Table 1**.

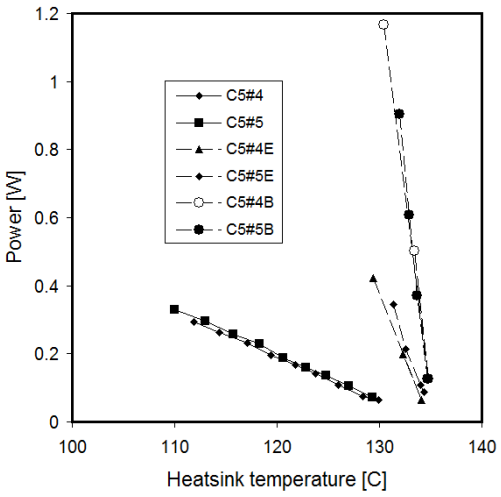

Fig. 9 - Measurements of dissipated power vs. heat-sink temperature for device C5 and peak, edge, and back temperatures.

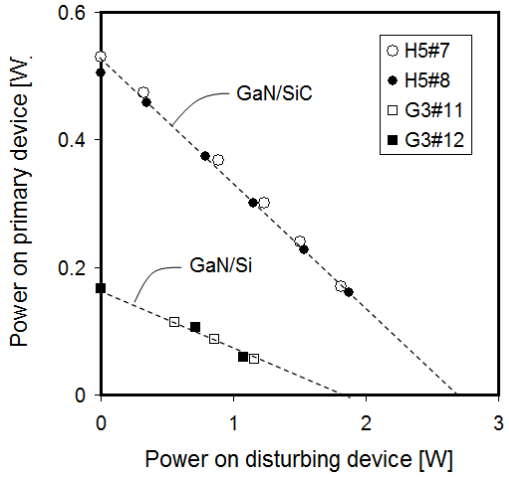

Fig. 10 - Thermal crosstalk raw data: power delivered to the primary device versus power delivered to the disturbing device for an exemplary GaN/SiC and GaN/Si device.

Device	Θ_P [°C/W]	Θ_C [°C/W]	s	Θ_E [°C/W]	Θ_B [°C/W]
GaN/Si	74 ± 3	10.1±0.3	0.1±0.02	11±2	4±1
GaN/SiC	30 ± 2	6.3 ±0.3	0.2±0.02	6±1	5±1

Table 1 - Summary of thermal-resistance measurements

V. Analytic Modeling

To extract the structure thermal parameters, we start by assuming a linear-resistor network model for the coupled-transistor structure and extract the individual thermal resistor values from the measured data. The proposed linear-resistor network is shown in Figure 11. This network has three unknowns and models the dominant heat-flow phenomena present in our structures: R_S, also referred to as *vertical thermal resistance*, is the thermal resistance between the transistor and the substrate provided no heat flows over to the other transistor - this is equivalent to powering both transistors at the same with equal power (and assuming their thermal resistance are identical, R_C is the *crosstalk thermal resistance*, while αR_S is the *source-local thermal resistance*, i.e., the part of vertical resistance contributed by the structure and layers close to the device where the crosstalk to the neighboring device may be assumed negligible. The intent of defining the source-local thermal resistance as not having any cross-talk component is to be able to separate the contributions to R_S coming from GaN/substrate TBR ($\sim\alpha R_S$) on the one side and the substrate, die attach, and the package ($\sim(1\text{-}\alpha)R_S$) on the other. This criterion is well satisfied for both devices tested here: the volume available for lateral heat flow in the substrate is orders of magnitude larger than that in the epilayers.

We assume that the structure is symmetric (and the experimental data confirm this). In this case, the peak temperature on device k (k = 1, 2) is given by $\Delta T_k = \Theta_k(P_k + sP_{1\text{-}k})$, where P_k is the power to the primary device, P_{1-k} power to the disturbing device, Θ_k the thermal resistance of device k when the disturbing device is off, and s the crosstalk coupling slope. With shorthand notation $R_C = \chi R_S$, we have

$$\Theta_k = R_S \frac{\chi + (1-\alpha)(1+\alpha)}{\chi + 2(1-\alpha)} \qquad s = \frac{(1-\alpha)^2}{\chi + (1-\alpha)(1+\alpha)} \quad (2)$$

From here we find the vertical thermal resistance as $R_S = (1+s)\Theta_k$. We then measure the temperature at the center of the chip Θ_C, exactly half-way between the two devices, and evaluate α using $\Theta_C = (1\text{-}\alpha)R_S/2$. Using α and s we then determine the crosstalk with

$$\chi = (1-\alpha)\left\{\frac{(1-s)-\alpha(1+s)}{s}\right\} \quad (3)$$

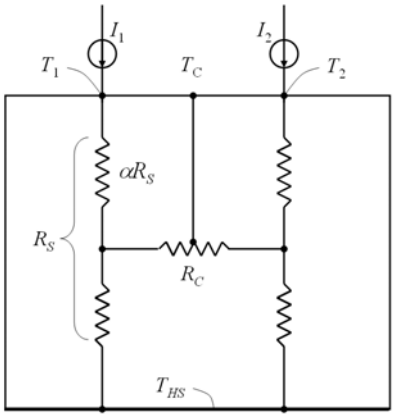

Fig. 11 - Linear thermal-resistor network model of the thermally-coupled-FET chip.

The analytic-model parameters extraction was done on data from a single device, rather than on the average value of thermal resistance shown in **Table 1**, in order to maintain consistency between the measurements when equations (2) and (3) were applied. **Table 2** shows a summary of the extracted parameters. The large difference between the R_C values confirms our expectation that SiC is significantly better heat spreader than silicon, while large value of αR_S for the GaN/Si device indicates that the thermal boundary

between the heat-source and the substrate for GaN/Si is higher than that of GaN/SiC.

The analytic model is good for qualitative comparison between different structures or different implementations of same structure. However, we are interested whether we can extract the value of *TBR* from the LCT measurements. This is shown in the next section.

Device	R_S K/W	R_C K/W	αR_S K/W	TBR_1 m²K/GW	h W/cm²K
GaN/Si	84	8.6	64	48	7.0
GaN/SiC	36	1.3	24	1.5	6.4

Table 2 - Summary of lumped model parameters

VI. Numerical Modeling

We use a three-dimensional heat-flow solver based on 2D-Fourier series expansion in the *x-y* plane and matrix generated Green's function in the z-direction. Our approach is conceptually the same as the approach described in reference [11]. The heat-source width was 3 um which is close to the resolution obtainable with LCT. In addition, in this range of heat source widths, the thermal resistance weakly depends on the heat source width. The other structure parameters are shown in **Table 3**.

The task of fitting structure physical properties to the measured Θ_P , Θ_C and s values is an incompletely defined problem. To reduce the number of free parameters (and unknowns), we first simplify the representation of the actual device structure. Our simplification consists of forcing a convection boundary condition at the bottom of the substrate. The heat transfer coefficient h is a single parameter that characterizes the cooling of the bottom of the chip. It includes the combined effect of the solder (thickness and thermal conductivity), heat flow through the heat sink below it, and the heat sink cooling efficiency. By doing this, we have neglected heat spreading in the solder layer and the heat sink. This approximation is justified for substrates that are (a) thicker than the separation between the two HEMTs, as in our GaN/Si case, and (b) for substrates with thermal conductivity much greater than the solder and/or heat sink below it, as in our GaN/SiC case. In both of these cases the lateral variation of the temperature along the bottom the substrate (and above the solder) is small. Furthermore, we assume that the thicknesses or the substrates and epilayers are known. To first order, thickness uncertainty can be treated as thermal conductivity uncertainty.

With this simplification, four free variables remain unknown: GaN epilayer thermal conductivity κ_{GaN}, substrate thermal conductivity (κ_{Si}, κ_{SiC}), heat transfer coefficient h, and *TBR*. Gallium nitride κ_{GaN} varies due to temperature, doping, and crystal purity: We select a center value and test the impact on the other parameters when we vary κ_{GaN} = 120 ± 10 W/mK. The thermal conductivity of silicon reduces with temperature and we observe the effect of its variation in the range κ_{Si} = 125 ± 25 W/mK. Similarly, silicon carbide substrate thermal conductivity varies in the range κ_{SiC} = 330 – 450 W/mK. For the heat transfer coefficient h, we first obtain a rough estimate (see next section) and then proceed with h and *TBR* as free variables to adjust.

There is a level of independence between h and *TBR* and the measured temperatures (thermal resistance): Modeled Θ_C is very dependent on h, but not on *TBR*. *TBR* has a dominant effect on Θ_P, while Θ_P weakly depends on h. Relative magnitude of s and Θ_C depends on h more than *TBR* and on the substrate thermal conductivity. Fine adjustment of h and *TBR* both has be done to make all three parameters fit. Note that, due to the uncertainty in the measurement, the modeled values of Θ_P, Θ_C, and s are adjusted until they fit the measured values to within two significant digits. However, at some marginal cases we had to accept less as the relationship simply could not be exactly fitted. We do not show results for the input parameters for which the reasonable fit to the measured values could not be obtained. They were outside our parameter space and are assumed to be outside of the simple model used for fitting.. Once a parameter combination that works is found, we proceed in varying the substrate and GaN thermal conductivities to observe the parameter space of all four free variables.

A rough estimate of the heat transfer coefficient can be obtained by measurement: As shown in **Figure 8**, the device is mounted in a package, which is attached to a nickel-plated copper heat spreader within which there is a thermocouple reading T_{HS}. The heat-spreader rests on top of a temperature-controlled hotplate. We measure the temperature difference between the chip edge T_B and the temperature measurement within the heat spreader T_{HS} to be 3 − 5°C/W. Since the chip area is around $3.05 \cdot 10^{-6}$ m² (1.4 mm x 2.175 mm). This means that the first-order estimate of the heat transfer coefficient is h = 6 − 10 W/cm²K. Note that this is the range of the maximum heat transfer coefficient. The devices were mounted using the same process and package (at the same time) and it is likely that the heat transfer coefficient will be close for the two devices.

Table 3 - Modeled structures with best fit parameters for highest temperature shown in Figure 12.

As a sanity check, note that the uniform thermal resistance of the package base, calculated from the chip area and the package base physical parameters, is about 1.2°C/W, while the copper below it would be ~ 8.2°C/W. It is hence reasonable to expect that due to heat spreading in the package base and the copper-block, this uniform thermal

resistance would reduce 2 to 3 times. The package base is made out of a copper alloy with thermal conductivity ~ 170 W/mK and thickness equal to 625 um. The heat-block below it is made out of copper with thermal conductivity ~ 400 W/mK. The interface between the two includes gold plating one both surfaces. The package is bolted solidly to the heat block and no thermal paste was used between the two. We also measured the cooling efficiency and the thermal time constant of the entire hot-plate/device system (the cooling of the stage is approximately exponential). The thermal resistance between T_{HS} and the ambient T_A is $\Theta_{HS\text{-}A}$ ≈ 9.6°C/W and the time constant τ_{TH} ≈ 780 seconds. These latter parameters ($\Theta_{HS\text{-}A}$ and τ_{TH}) do not enter into the modeling.

The central result of this work is shown in Figure 12 where we show how the best fitting values of TBR_1 and h vary with substrate and GaN thermal conductivity. Clearly, the TBR_1 values extracted for GaN/Si are quite large: If we assume that the silicon thermal conductivity is reduced at 400K to between 100 and 110 W/mK, the extracted TBR_1 values falls between 48 and 60 m²K/GW. This is larger than published values 33 m²K/GW [4], but reasonable as the thermal boundary resistance contributed by the nucleation layers depends very much on the specific design and growth parameters which vary between different manufacturers. Similar conclusion holds for GaN/SiC device where we measured a very low TBR, among the lowest reported [1].

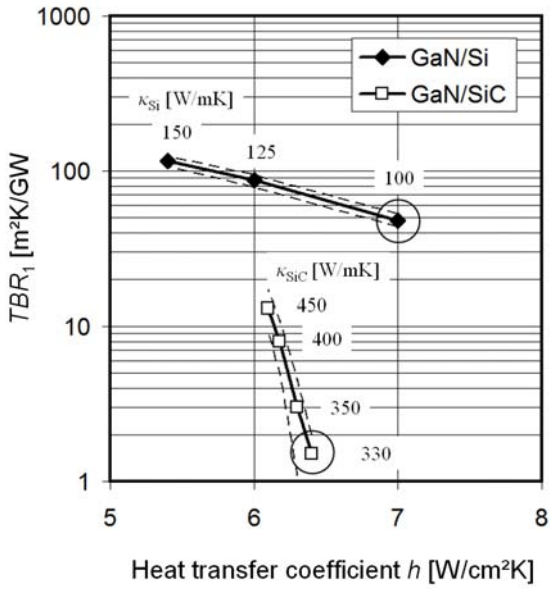

Fig. 12 - Fitted values of *TBR* and *h* that give matching Θ_P, Θ_C, and *s* while the thermal conductivity of the substrate is varied. Circled values correspond to highest temperature (~400K)

VII. Conclusion

Liquid crystal thermography is a method generally used for measurement of surface temperature. However, with suitable heat source geometries and measurements of temperature at multiple surface locations one opens the possibility of estimating the thermal properties of sub-surface structures. The certainty of the estimated thermal parameters greatly depends on the complexity of the semiconductor device and the knowledge of all other structure parameters. We used thermal cross-talk between two adjacent high-electron mobility transistors and the surface temperature measurement at the heat sources and between the two transistors to estimate thermal boundary resistance between the GaN epilayers and the substrate for GaN/Si and GaN/SiC transistors. This approach results in temperature values at multiple surface points and hence allows for precision in fitting to analytic or numerical models. Relative to other methods used for estimating thermal boundary resistance, LCT offers significantly greater simplicity in the measurement and a significantly lower overall test-system cost.

***Abstract*—This paper presents the design of a planar inductor for a DC-DC converter for flexible foil applications. The design challenges related to the flexible foil structure and the DC-DC converter requirements are analysed. The main design challenges are due to the constraints on the inductor physical size, the proximity of a conductive plane to the inductor and very high operating frequency of the DC-DC converter. The methodology of the inductor design is based primarily on EM simulations of the inductor structure and on the evaluation of the simulation results in the context of the resulting lumped-element electrical model. The simulations are verified by measurements of the inductors processed on the FR4 substrate which presently emulates the flexible foil substrate.**

***Index Terms*—thick film inductor, electromagnetic modelling**

I. Introduction

A. State of the art

The electronics on flexible foils is getting popular as it offers new innovative applications in the areas of wearable electronics, lightning devices and displays [1]–[4]. Such applications require power supplies embedded in the flexible foil. Switching-mode power supplies are a de-facto standard in the present DC-DC power conversion applications [5].

Switching-mode power supplies require an energy storage element to work properly and inductors are often used to fulfil the required function. In the case of the flexible foil applications this inductor has to be embedded on the foil as well. Usually, a planar inductor design based on spiral geometry is used. Spiral planar inductors are modelled and characterized quite well [6]–[9].

Many conclusions based on the research of planar inductors processed on the Si substrate in the integrated circuits can be applied on the inductors implemented in the flexible foil technology, but some specific power applications in the flexible foil can pose a set of unique design challenges.

B. Design challenges

The inductor is designed for a buck-type DC-DC converter that drives an OLED tile realized on the flexible foil. Numerous design challenges are related to designing an inductor for a flexible foil application.

The constraints placed on the physical size of the inductor are one of the design challenges. The most obvious physical constraint is the thickness of the metal layer the inductor is patterned in. Flexible foil application of the inductor implies a planar layout of the inductor as the multi-layered layouts are unrealisable because of the limited total thickness of the foil. The physical constraint specific to this implementation is the limited available area for the placement of the planar inductor. The OLED tile size ranges from 30 x 30 to 125 x 35 mm^2 and an inductor must be placed on the area of a single OLED tile. The area enveloped by an inductor is closely related to the maximally realizable inductance of the inductor thus the available area for the placement of the inductor is an important design challenge.

The structure of the OLED tile and its application in a flexible foil presents the next specific design challenge. In the context of the inductor design the cathode of the OLED tile represents a uniform metal plane acting as a ground plane. This ground plane is only separated from the inductor by a thin foil. A ground plane in close proximity to the inductor presents a design challenge as the inductor currents are mirrored over the ground plane. The mirrored currents, i.e. eddy currents reduce the total magnetic flux induced by the inductor and consequentially the total self-inductance of the inductor.

The requirements of the DC-DC converter in the context of the electrical characteristics of the inductor are the next important design challenge. The value of the inductance of the inductor is vital to the operation of the DC-DC converter. The resistance and the parasitic capacitance of the inductor directly affect the efficiency of power conversion. The inductor has to preserve its inductive properties in the frequency range that covers the switching frequency of the converter as well as the first few higher harmonics of the driving PWM signal. It sets a requirement on the dynamic behaviour of the inductor, namely that the resonant frequency of the inductor needs to be beyond that frequency range. The planned DC-DC converter places the inductor requirements that are shown in Table I. It should be noted that the maximum resistance requirement will be treated as a requirement placed on the DC value of the inductor resistance because the OLED tile behaves primarily as a capacitive load thus stabilizing the current that runs through the inductor and minimizing its ripple component.

II. Materials and methods

A. Electromagnetic simulations

The described flexible foil substrate requires a planar inductor structure because of its thin geometry. The thin inductor structure is simulated in the COMSOL Multiphysics. Its RF module is used as the 3D EM solver for this problem.

This work was supported by the European Commision under the Seventh Framework Programme (FP7) through project IMOLA Intelligent light management for OLED on foil applications (Grant Agreement No. 288377).

TABLE I
THE INDUCTOR REQUIREMENTS OF THE DC-DC CONVERTER

Electrical characteristics	Required value
Series inductance, L_s	3 to 5 μH
Series resistance, R_s	$< 1\ \Omega$
Parasitic capacitance, C_p	< 50 pF
Resonant frequency, f_r	> 50 MHz

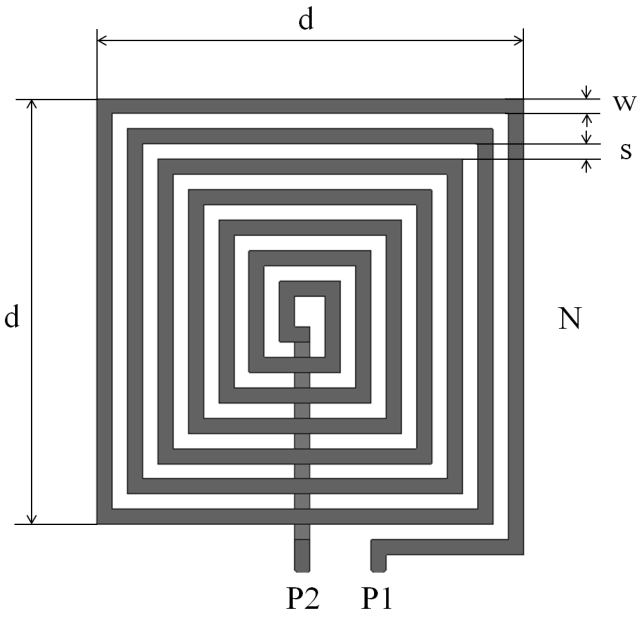

Fig. 1. The geometry of the inductor model used in the electromagnetic simulations.

The geometry of the model used in EM simulations is based on the smallest OLED tile dimensions as it represents the worst case scenario in the context of the inductor total area and thus its inductance. The inductor model is based on a spiral rectangular geometry and it is shown in Fig. 1. The geometry is determined by the outer diameter of the rectangular spiral d, the track width w, the track spacing s and the number of turns of the spiral N. The positions of the ports P1 and P2 are also marked in the figure. The simulated substrate has two dielectric layers and three metal layers. The inductor is wound in M1 (top metal) and the exit towards the port P2 is performed in M2 layer. The bottom metal M3 serves as the ground plane if it is used.

The operating frequency of the DC-DC converter determines the frequency range of interest that is analysed in EM simulations. The inductor is driven by a PWM signal from the DC-DC converter which is essentially a rectangular waveform. The analysed frequency range includes the switching frequency of the converter and its higher harmonics and it is determined by the frequency from 1 to 200 MHz. The upper frequency limit is set to include the resonant behaviour of the inductor in the analysis.

The electromagnetic simulations are primarily used to investigate the influence of the different design parameters on the electrical characteristics of the inductor. The design parameters are swept in different ranges. The values of the design parameters are shown in the Table II.

TABLE II
THE VALUES OF THE DESIGN PARAMETERS

Design parameter	Range value
Track width, w	0.25 to 2 mm
Track spacing, s	0.25 to 1 mm
Number of turns, N	1 to max.
Outer diameter, d	28 mm (const.)
Track metal	Cu
Track thickness	35 μm
Top/bottom dielectric thickness	200 μm

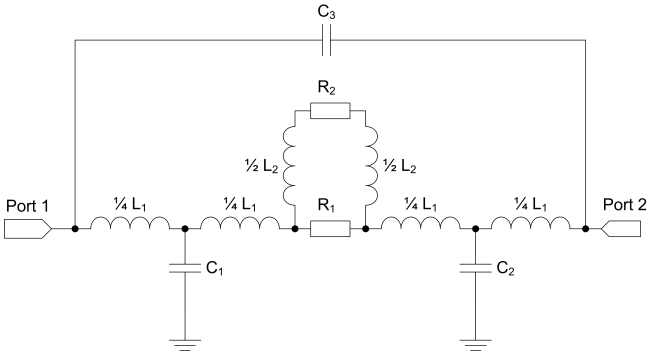

Fig. 2. The π-model of the inductor that accounts for the port and interport capacitances and the skin effect.

B. Electrical model

A lumped-element electrical model is developed to evaluate the electrical characteristics of the inductor in the context of the requirements and to accurately describe the behaviour of the inductor in the frequency range relevant to the operation of the DC-DC converter.

In the analysis of the simulation and measurement results a π-model was used and its topology is shown in Fig. 2. The π-model consists of the port capacitances C_1 and C_2, the interport capacitance C_3, the interport inductance L_1 and the ladder network R_1-R_2-L_2. The capacitances C_1, C_2 and C_3 account for different resonances of the inductor while the ladder network R_1-R_2-L_2 describes the frequency dependant resistance of the inductor, i.e. the skin effect present at the operating frequency of the DC-DC converter [10].

Physically, the capacitances C_1 and C_2 represent the capacitances of the inductor tracks towards the ground plane. As the geometry of the inductor tracks is asymmetrical in the context of its ports, it is expected that the capacitances C_1 and C_2 are not equal. The capacitance C_3 represents the interwinding capacitance of the inductor.

The parameters of the electrical model are extracted using a developed algorithm implemented in MATLAB. The algorithm is described by the flowchart shown in Fig. 3. The algorithm is based on three steps. In the first step the inductance L_1 is calculated from the interport impedance. In the following step the capacitances C_1, C_2 and C_3 are calculated from the resonant and antiresonant frequencies. The third step is based on fitting the ladder network R_1-R_2-L_2.

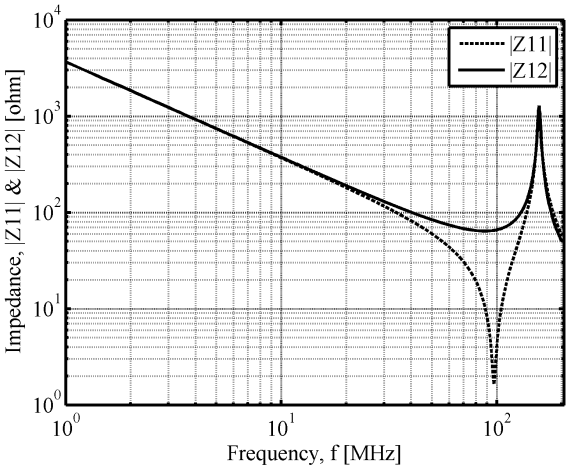

Fig. 5. The amplitude frequency characteristics of the Z_{11} and Z_{12} parameters for the simulated data.

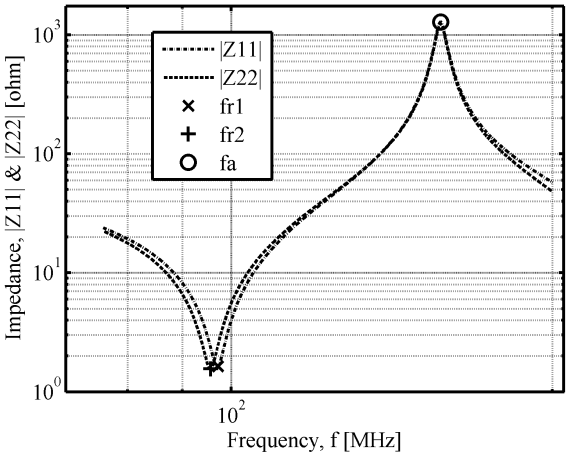

Fig. 6. The amplitude frequency characteristics of the Z_{11} and Z_{22} parameters for the simulated data with marked resonant frequencies.

C. Physical verification

The results of the electromagnetic simulations are verified by measurements of the inductors. The inductors are processed on the FR4 substrate. The FR4 substrate has two 200 μm thick dielectric layers and can be considered a good emulation of a flexible foil substrate.

Multiple inductors with varied track width and spacing are processed in the form of a matrix. The track widths are 0.5 mm, 1 mm and 2 mm and the track spacing 0.25 mm, 0.5 mm and 1 mm. Both variations are made simultaneously thus accounting for 9 unique inductor designs, as shown in Fig. 4. The same layout is processed in two versions. The first version is realized as a PCB with a single FR4 layer and two layers of metallization, while the second version was realized with an additional FR4 layer with a metal sheet. This metal sheet acted as the ground plane.

The measurements are made using a vector network analyser. The ports used in the layout are designed to allow their de-embedding at the reference plane Δ-Δ′ shown for the top-left inductor in Fig. 4. A separate layout was developed and used for the Short-Open-Load-Through (SOLT) calibration of the vector network analyser.

III. Results

A. Frequency characteristics

The frequency characteristics of the inductor are analysed on the inductor example determined by the following set of design parameters w = 1 mm, s = 1 mm, N = 7. The results of the electromagnetic simulations in the context of its Z-parameters are presented in Figs. 5 and 6.

In Fig. 5 the frequency characteristics of the Z_{11} and Z_{12} parameters are presented. Several resonant frequencies can be identified in these characteristics. The frequency characteristics of the interport impedance Z_{12} has a single local maximum that can be identified as antiresonant behaviour. This implies a parallel LC network between the ports of the inductor which is presented in the electrical model with the interport capacitance C_3 (Fig. 2). The frequency characteristic of the port impedance Z_{11} has two local extremes. One extreme is a local maximum and matches the previously identified antiresonant behaviour of Z_{12} and the second extreme is a local minimum. This local minimum can be identified as resonant behaviour and implies the existence of the port capacitances. These port capacitances are presented in the inductor model by the capacitances C_1

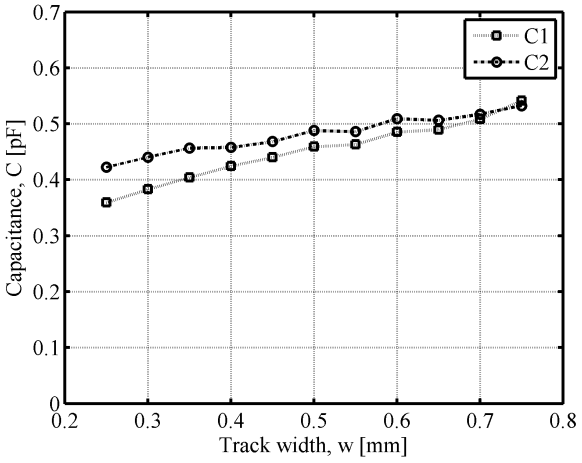

Fig. 7. The dependence of the port capacitances C_1 and C_2 on the track width with total turn spacing $s + w$ = 1.25 mm and N = 11.

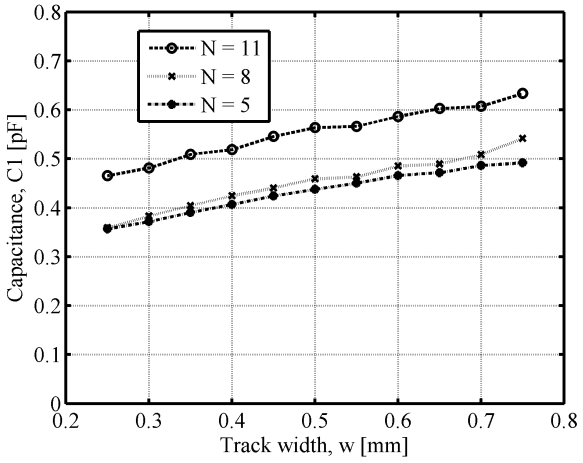

Fig. 8. The dependence of the port capacitances C_1 in the context of the track width and the number of turns of the inductor with total turn spacing $s + w$ = 1.25 mm.

and C_2.

The frequency characteristics of the Z_{11} and Z_{22} port impedances are compared in Fig. 6. The identified resonant and antiresonant behaviour is emphasized by separate markers. It is to be noted that the antiresonant frequency f_a is identical for both ports, but the resonant frequencies f_{r1} and f_{r2} are slightly different. This was expected as the port capacitances C_1 and C_2 are also slightly different because of the asymmetrical inductor structure.

In the context of the DC-DC converter requirements the resonant behaviour of this inductor design example is well above the required frequency limit of 50 MHz.

B. Design parameter sweeps

The design parameter sweeps are the primary method of exploring different inductor designs. The parameter sweeps described in the methodology of this work yield a large database of simulation results. The analysis of this database is presented in a series of figures that represent only a selection of simulation results and are later used for defining a set of design guidelines for the planar inductors.

Figs. 7, 8 and 9 show the dependences of the electrical model capacitances C_1, C_2 and C_3 w.r.t. different design parameters, while Fig. 10 shows such a dependence of the series inductance L_s.

The port capacitance dependence on the track width and the interrelationship of the port capacitances C_1 and C_2 is shown in Fig. 7. Two observations of the results are made. The first observation is that the port capacitances are not equal. This asymmetry of the port capacitances is in accordance to the asymmetric inductor structure. The second observation is that the value of the port capacitances is proportional to the track width. As the total spacing of the turns $(s+w)$ and the number of turns are kept constant, the track width in this figure can be directly correlated with the total track area. This observation is expected because the capacitance of a capacitor is directly proportional to the area of its plates.

The port capacitance C_1 dependence on the track width and the number of turns is shown in Fig. 8. In this figure the observation concerning the port capacitance dependence on the track width from Fig. 7 is confirmed. This observation

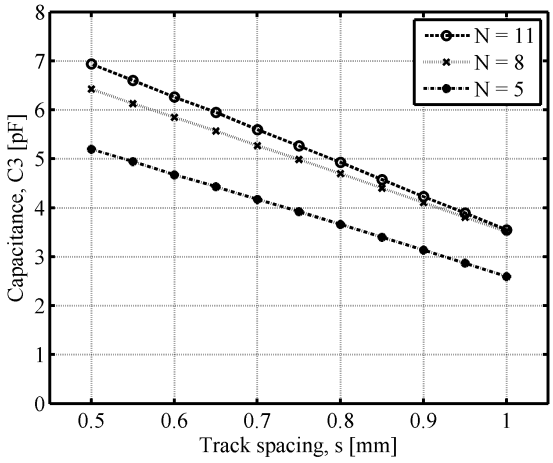

Fig. 9. The dependence of the interport capacitances C_3 in the context of the track spacing and the number of turns of the inductor with total turn spacing $s + w$ = 1.25 mm.

is expanded with the dependence on the number of turns. The dependence of the port capacitance on the number of turns is expected because increasing the number of turns increases the total track area as well. This effectively increases the plate area of the capacitor that represents the port capacitance in conjunction with the ground plane.

The interport capacitance C_3 dependence on the track spacing and the number of turns is shown in Fig. 9. Two observations are made based on this figure. The first observation is that the interport capacitance is inversely proportional to the track spacing. The interport capacitance is based primarily on the capacitance between neighbouring inductor turns. It is expected that, if the space between the tracks is increased while maintaining the same track length, the capacitance is decreased. The second observation is similar to the observation of the port capacitance dependence on the number of turns. The interport capacitance is increased as the number of turns is increased and thus the length of the tracks is increased. It should be noted that the dependence of the interport capacitance on the number of turns is nonlinear because the dependence of the track length on the number of

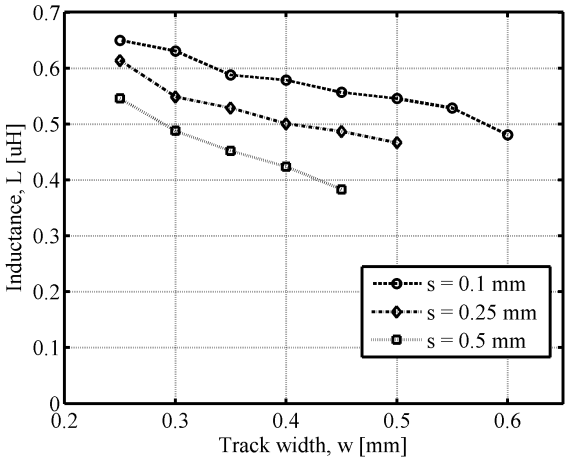

Fig. 10. The dependence of the series inductance L_s in the context of the track width and the track spacing while maintaining the series resistance constant R_s = 1 Ω.

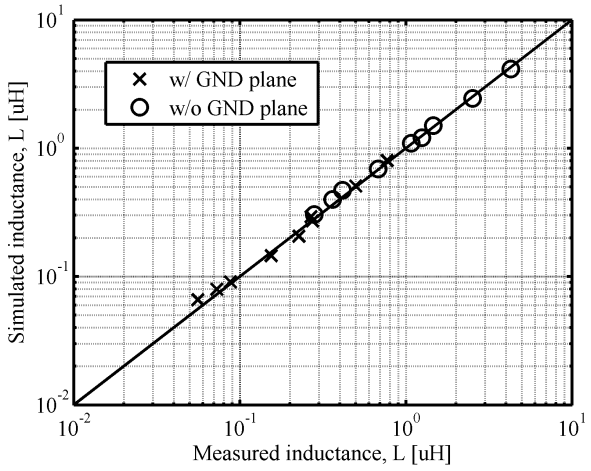

Fig. 11. The correlation between the measured and simulated data in the context of the extracted inductance of the inductor.

turns is nonlinear as well, i.e. the inner turns of the inductor spiral contribute the least to the track length.

The dependence of the series inductance L_s on the track width and the track spacing is shown in Fig. 10. These simulation results are made in the context of the DC-DC converter requirements for the series resistance of the inductor. The required number of turns to achieve the upper resistance limit for each combination of the track width and track spacing was calculated and used in the simulations. An observation is made based on these results. The inductance achievable in the context of the resistance requirement is at the maximum for the combination of minimal track width and minimal track spacing. When the track width and/or the track spacing increase, the inductance of the inductor decreases. This observation is interpreted by understanding that a narrower turn with minimal spacing can envelope a greater area and thus produce greater inductivity. Another effect should be considered; while the wider turns can support a greater number of turns in the context of limited inductor resistance, the number of turns in the case of a planar inductor suffers from the effect of diminishing returns. The inner turns are contributing the least to the total inductance of the planar inductor.

In the context of the DC-DC converter requirements the capacitances of the inductor are significantly lower than the required maximum capacitance, while the inductance is below the required range of values.

C. Physical verification

The results of the electromagnetic simulations are verified by measuring a set of inductors with different design parameters. The results of the physical verification are presented in Figs. 11 and 12. These figures show the correlations between the measured and simulated data.

The correlation of the extracted inductance L of the inductor is given in Fig. 11. The simulated inductance correlates with the measured inductance well.

The effect of the metal plane on the inductance and the resonant frequency can be observed in these results. As expected introducing the metal plane in the substrate of the designed inductors decreases its inductance approximately

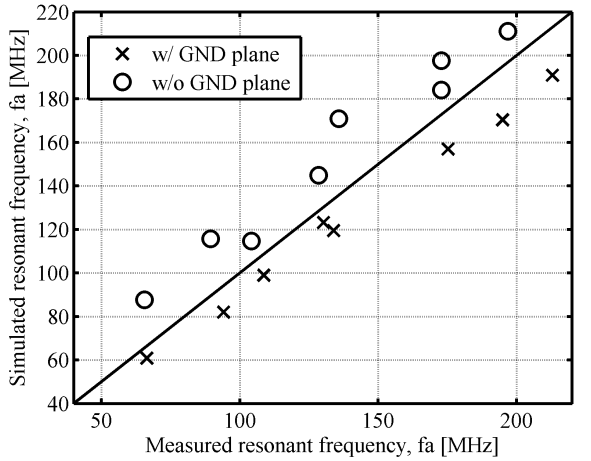

Fig. 12. The correlation between the measured and the simulated data in the context of the resonant frequency of the inductor.

by a factor of 5 because of the mirroring of the inductor currents and reduction of the magnetic flux.

The correlation of the resonant frequency f_a is shown in Fig. 12. The simulated resonant frequency correlates with the measured resonant frequency rather well with a slight offset. The probable cause to the offset is the uncertainty of the processed substrate thickness compared to the one used in the simulations.

In the context of the DC-DC converter requirements the inductance of a few inductor designs without the metal plane falls within the required range of values. With the introduction of the metal plane in the substrate design, none of the design cases conform to the requirements, i.e. the inductor is too small.

IV. Discussion

A. Design guidelines

Based on the observations made on the results of the simulations several guidelines for designing a planar inductor can be set. Each guideline corresponds to a single design parameter of the inductor.

The first design guideline corresponds to the track width. Based on the observations of the results the track width

should be minimized. This guideline minimizes the value of the port capacitances and maximizes the value of the inductance in the context of the required inductor resistance.

The second guideline is related to the track spacing. The observations of the results imply that the track spacing should be optimized between the requirements on the resonant frequency and the requirements on the inductance. The resonant frequency of the inductor is closely related to the value of the interport capacitance. If the requirements on the resonant frequency are more relaxed, then the general guideline is to minimize the track spacing in order to maximize the inductance of the inductor.

The third guideline is based on the number of turns. The results have shown that the increased number of turns increases the parasitic capacitances of the inductor thus a smaller number of turns of the inductor is more desirable. In the context of the resistance requirement, narrower tracks with smaller spacing have a smaller number of turns than the wider tracks with greater spacing. Coincidently the narrower turns with smaller spacing are more desirable in the context of the inductance.

To sum up, the number of turns should be minimized which can be indirectly achieved by minimizing the track spacing and the track width while respecting the resistance requirement.

B. Further development

The results have shown that the metal plane in close proximity to the inductor severely degrades its inductance. This ground plane effect is due to the inductor currents mirrored in the metal plane. There are several possible ways to shield the inductor from the metal plane and its degrading effects.

One possible solution is the application of patterned ground shields (PGS) [11]–[13]. These shields are an additional conductive layer between the inductor and the metal plane which is patterned in such a way that the path of the induced eddy currents is effectively broken.

Another possible solution to the ground plane effect problem is the application of the ferrite polymer composite (FPC) layer between the inductor and the metal plane [14]–[16]. This FPC layer, because of its significant permeability, literally shields the inductor from the metal plane.

The described solutions have the potential to restore the inductance of the inductor to the values present in the substrate cases without the metal ground plane below inductor. Further inductance enhancement can be achieved by applying an additional FPC layer above the inductor structure thereby creating a well-defined magnetic path for the magnetic flux induced by the inductor.

V. Conclusions

The design of the planar inductor for DC-DC converter applications is presented. The design is primarily based on investigating the design parameters by electromagnetic simulations. An electrical model is used to analyse the results of the simulations. An algorithm used to extract the electrical model parameters is presented. The electromagnetic simulations are physically verified by measuring the inductor designs processed on the FR4 substrate. Based on the analysis of the results a set of design guidelines is presented. The design guidelines recommend minimizing the track width and the track spacing while adapting the number of turns to the resistance requirement to achieve the maximal inductance. The degrading effect of the ground plane on the inductance of the inductor is analysed. The solutions using the patterned ground shields or ferrite polymer composite are proposed.

Abstract - Teaching electric circuit theory involves the use of Ohm's and Kirchhoff's laws; branch, mesh and node analysis, as well as AC analysis and transient analysis. The latter gives the most comprehensive insight into circuit behavior.

When analytical transient circuit analysis is used, one needs to solve the differential equations that describe the circuit behavior. Electrical engineering students often find this difficult.

Alternatives to the mathematical analysis are: a) the simulation of the given problem with a commercial circuit simulator, and b) building a physical circuit, the behavior of which can then be observed and analyzed. These approaches are most productive when optimizing the behavior of a circuit, but they can easily add their own noise to the circuit study.

The presented approach for the effective transient analysis is by simulating equations. The circuit in question is analyzed using Kirchhoff's laws with reference to specific time slices. The equations describing circuit components that store energy (capacitors, inductors) are then used to connect the consecutive time slices.

The coding of equations for a given circuit allows students to gain a thorough understanding of the circuit's workings. Test cases show that results match perfectly between the simulation of equations and the analytical results from different RLC example circuits.

Keywords: **electronics education, electrical circuit simulation, simulation of equations, time variant circuit, transient response**

I. INTRODUCTION

The fundamental tools used in analysis of electric circuits are Ohms', Kirchhoff's voltage and Kirchhoff's current law. They are explained in practically every electrical engineering [1,3] and physics book [5]. Scholars learn yet in the primary school that the current through the resistor is proportional to voltage and inversely proportional to resistance. It is taken as self-evident that the sum of the currents that enter the node equals the sum of the currents that exit the very same node. It is also understood as granted that the battery voltage appears on the resistor when both are interconnected.

In the physics classes of the secondary school students re-learn that the three »self-evident« phenomena described above are laws of the electric theory, which have important physics background. They start relating the Kirchhoff's voltage law to conservation of energy and the Kirchhoff's current law to conservation of electrical charge.

At this level, students are able to calculate voltages, currents, resistor values and power in electric circuits that are built from the voltage sources, current sources, resistors, light bulbs and similar devices.

Understanding functioning of capacitors and inductors takes more than application of the three most fundamental laws of electrical engineering to the circuit. Using algebra only is not enough for the analysis since the capacitors and inductors store energy. A dimension of time needs to be introduced into equations since power, integrated over time is needed for the changes of energy in the capacitors and inductors. The equations (1) and (2) state the relations among relevant quantities in the capacitor and in the inductor.

$$i_C = \frac{\partial Q_C}{\partial t} = \mathrm{C}\,\frac{du_C}{dt} \tag{1}$$

$$u_L = \frac{\partial \emptyset_L}{\partial t} = \mathrm{L}\,\frac{di_L}{dt} \tag{2}$$

In (1), Q_C stands for the electric charge on the plates of the capacitor, C stands for capacitance.

In (2), $\emptyset_L$ stands for magnetic flux built around the inductor, L stands for inductance.

Diodes have non-linear behavior. They can be modeled as piece wise linear devices being implemented as resistors.

Active devices which represent all sorts of different types of semiconductor devices with current or voltage gain, can be modeled as small electric circuits consisting of resistors, capacitors, inductors, voltage controlled voltage and current sources, current controlled current and voltage sources. This all is comprehensively covered in many books on electrical engineering, such as [2].

In the Direct Current (DC) analysis, many circuits can be analyzed by using only algebra and the three fundamental circuit laws (Ohms', and the two Kirchhoff's laws). When this approach does not suffice then some additional methods are available, namely the superposition, Norton's, Thevenin's theorem, Delta Wye conversion, theorem on maximum power transfer and similar. They do not introduce additional mathematical complexity.

As circuits consist of more elements then some systematics is needed in the analysis. When one builds a computer program for circuit analysis, a systematic approach to the analysis is mandatory. The three methods that were developed for the purpose, are branch, mesh and node analysis. They build only on the three fundamental circuit laws of the DC analysis, but they do enforce use of strictly defined procedures which lead to systems of independent linear equations that describe the circuit. There are many techniques and available tools for solving the resulting set of linear equations [4].

As energy storage devices, i.e., capacitors and inductors are introduced to the electric circuit, the three fundamental circuit laws still do apply, but (1) and (2) become part of the mathematical description of the circuit. Algebraic equations get substituted for differential equations. A most simple example of charging the capacitor via the resistor from the voltage source in Figure 1 reminds us on the relatively complex approach which is needed to calculate the circuit variables.

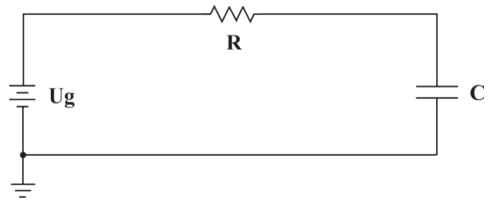

Figure 1. Schematics of a circuit where a capacitor C is charged from the voltage source Ug. Resistor R is limiting the charging current.

Equation (3) represents application of the Kirchhoff's voltage law – sum of the voltages in a closed loop equals zero:

$$V_G = \mathrm{V_R} + V_C = IR + V_C = R\frac{dQ}{dt} + \frac{Q}{C} \qquad (3)$$

The essential steps that lead to the time dependent expression for the voltage on the capacitor are:

The

$$V_G = R\frac{dQ}{dt} + \frac{Q}{C},$$

can be multiplied by C and rearranged into

$$RCdQ = (CV_G - Q)dt$$

$$\frac{dQ}{CV_G - Q} = \frac{dt}{RC}$$

Integration on both sides results in

$$-\ln(CV_G - Q) = \frac{t}{RC} + A,$$

Multiplying by -1 and applying the operator e^x on both sides results in

$$CV_G - Q = e^{-\frac{t}{RC} - A} = Be^{-\frac{t}{RC}},$$

$$Q = CV_G - Be^{-\frac{t}{RC}}$$

After applying the initial condition $Q = 0$ @ $t = 0$ one gets

$$B = CV_G$$

and

$$Q = CV_G(1 - e^{-\frac{t}{RC}}) = Q_{final}(1 - e^{-\frac{t}{RC}})$$

Application of $Q = CV$ gives the result

$$V_c(t) = V_G(1 - e^{-\frac{t}{RC}}), \qquad (4)$$

Some mathematical experience is needed to derive the result (4) from the equation (3). Once having the procedure written, it can be easily learned. The students' problem is that different circuit topologies result in different types of differential equations. The procedure for solving one type of a differential equation, which describes one circuit is not directly applicable for solving another type of a differential equation. One can learn many procedures or one can be mathematically gifted enough to make the necessary steps on the fly for the particular circuit.

As circuits get complex one needs to solve a set of differential equations to calculate the variables. This is more a problem of the mathematical analysis then of the electrical engineering. A more productive approach to the analysis, synthesis and optimization of the electrical circuits is needed for the daily work.

Use of phasors and complex numbers is the productive alternative, compared to the use of differential equations in analysis of the electric circuits. The limitation of the analysis with phasors and complex numbers is that it works only for signals of a sinusoidal form. The approach is based on the fact that the derived sine signal preserves the original form. Deriving sine(ωt) by t results in a cosine(ωt), which can be substituted with the sine($\omega t + \pi/2$). Initial function is preserved, only a delay, or phase shift of a $\pi/2$ is introduced. The complex numbers are used

to simultaneously calculate amplitude ratios and phase delays.

II. ELECTRIC CIRCUIT SIMULATION

Simulations of electrical circuits got possible and at the same heavily needed at a certain level of maturity in development of the semiconductor manufacturing processes. The computer platforms had to get developed up to a certain level to make development of circuit simulations possible.

Microprocessors had to be developed first. This gave the material substance for writing software compilers. Both, the first microprocessor and the first C compiler were developed in the fifties of the previous century.

The necessity for simulation stems from the intense development of technologies for production of the Integrated Circuits (ICs). it is not possible to explore functionality by probing internal nodes of such circuits. Only Input and Output (IO) pins can be reached with electric probes. This presented a huge problem at the onset of a semiconductor industry.

After having the computer platform, and the compiler available, practical work on the development of circuit simulators started. From the very beginning there are two conceptually different approaches to circuit simulation – one is for the digital and the other is for the analog circuits. The first one is a discrete event type simulation, where logic rules are simulated together with simplified transition delays between the logic states. The analog simulation mimics the circuit in a continuous time. Simulation of equations, which is the topic of this paper, simulates the circuit in a semi continuous time.

The origin of all modern analog circuit simulators is Simulation Program with Integrated Circuit Emphasis (SPICE). It has gone through different phases of a gradual development at the Berkeley University in the time from sixties till eighties in the past century.

SPICE was named an IEEE Milestone in 2011 which represents the IEEE recognition of the key historical achievement in electrical and electronic engineering. The modern IC manufacturers have their own teams to develop their internal versions of the SPICE simulator. Student versions of different SPICE derivatives are available at moderate cost. They have limitations on the size of the simulated circuit and they include only a limited set of available devices for build-up of the circuit. Fully loaded industrial versions of SPICE derivatives are usually leased to circuit design companies for a monthly fee.

Use of a simulator does help to speed up the learning process. There are some substantial inadequacies associated with learning the circuit theory by simulation only. Simulation tools introduce their own noise to the process of learning. Numerical methods are complex, not all simulation runs converge to solutions. When results are not in the realm of expected, it takes an experienced engineer to detect the cause of a discrepancy between the expectation and the result of simulation.

It is authors' understanding, after some 10 years of using SPICE in the field of the IC design, that use of the simulator adds in the highest extent to the circuit optimization. Relying on simulation results when not thoroughly understanding operation of the simulated circuit is not an acceptable option.

Modern SPICE based simulation tools are built from close to one hundred thousand lines of code. It takes an experienced programmer and the publicly available documentation to get enough insight into inner workings of these tools for optional modifications.

III. EXPERIMENTAL WORK

Expertise from the two different technical fields – electrical engineering and programming is employed to reach a better insight into the understanding and evaluation of electric circuits.

Deriving the transient analysis equations from the differential equations that describe the circuit, shifts the engineering effort from electrical engineering to mathematics. As the resulting equations finally get derived, one can think of how to interpret them in the terms of electrical engineering.

The proposed approach for gaining insight into the working of electric circuits relies on computer use for performing iterative calculations in loops, and on physical interpretation of the two differential equations, specifically the equations (2) and (3).

The basic statements of the approach are:

a) Simulation of equations has potential for gaining insight into operation of the analyzed circuit.

b) Only the current time data and the data at the time just before the current time suffice for the transient analysis at the current time.

   In the DC analysis there is no time involved. Ohms' and Kirchhoff's laws are not related to time. Circuits' DC behavior is valid for any time, which includes the current time.

   For elaboration on "the time just before the current time" one recalls the equations (1) and (2). The equation (1) can be rewritten as

$$u_C(t+dt) = u_C(t) + \frac{i_c(t)dt}{C} \tag{5}$$

   and equation (2) can be rewritten as

$$i_L(t+dt) = i_L(t) + \frac{u_L(t)dt}{L} \tag{6}$$

Equations (5) and (6) can present coupling between the current time $t + dt$ and the time just before the current time, which is time t.

Two important implications result from this understanding of (5) and (6):

- A capacitor represents a voltage source in the current time $t + dt$.
- Inductor represents a current source in the current time $t + dt$.

c) DC analysis only can be applied to calculate variables of an arbitrary electrical circuit at any specific moment in time. Capacitors represent voltage sources and inductors represent current sources at that moment in time. Ohms' and Kirchhoff's laws, procedures of branch, mesh and node analyses give the means for the DC analysis at that moment in time.

d) Use of equations (5) and (6) makes the transition in time from the DC circuit analyses at time *t* to the DC circuit analysis at time *t + dt.*

e) Effectiveness of the simulation will depend mostly on two parameters. One is the size of the time increment *dt* and the other is the calculation precision.

One can experiment with the time increment *dt*. Currents and voltages are defined as double precision variables since the case studies are programmed in the C programming language.

A. Simulation of equations that describe fluctuations of the capacitor voltage in the RC circuit

Applying the statements b) to d) of the proposed approach, one can write the equations (7) and (8) for description of the circuit in Figure 1:

$$i(t) = \frac{U_G - u_C(t)}{R} \tag{7}$$

$$u_C(t + \mathrm{d}t) = u_C(t) + \frac{i(t)\mathrm{d}t}{C} \tag{8}$$

Equation (7) states the Kirchhoff's voltage law – sum of the voltages in a closed loop equals zero. Equation (7) is valid for any time. All the variables in the equation (7) belong to the same time. Time has no influence on behavior that is described by (7). Current through a resistor that is connected between the two voltage sources with different voltages, is calculated in (7). One voltage source is the battery, the other voltage source is the capacitor.

Equation (8) is the bridge in time from the current time *t* to the time just after the current time, which is *t + dt*.

One can perform the DC analysis at time *t* by (7) and walk from the time *t* to the time *t + dt* by (8). When (7) and (8) are executed sequentially in a program loop where *t + dt* is changed for *t* in each iteration then the iterative simulation of equations (7) and (8) calculates transient response of the Figure 1 circuit.

B. Simulation of equations that describe fluctuations of the electric current through the inductor in an RL circuit

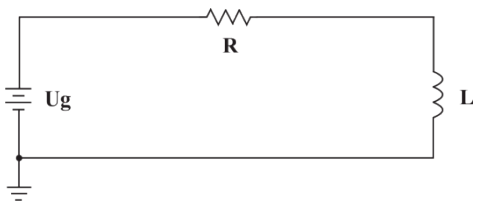

Figure 2. Schematics of an RL circuit connected to a voltage source.

Applying the statements b) to d) of the proposed approach, one can write the equations (9) and (10) that describe the circuit in Figure 2:

$$u_L(t) = U_G - Ri(t) \tag{9}$$

$$i(t + dt) = i(t) + \frac{u_L(t)dt}{L} \tag{10}$$

Equation (9) states the Kirchhoff's voltage law – sum of the voltages in a closed loop equals zero.

Equation (10) is the bridge in time from the current time *t* to the time just after the current time, which is *t + dt*.

One can perform the DC analysis at a time *t* by (9) and walk from the time *t* to the time *t + dt* by (10). When (9) and (10) are executed sequentially in a program loop where *t + dt* is changed for *t* in each iteration then the iterative simulation of equations (9) and (10) calculates the transient response of the circuit in Figure 2.

C. Simulation of equations that describe oscillations of the capacitor voltage and of the inductor current in the oscillating circuit

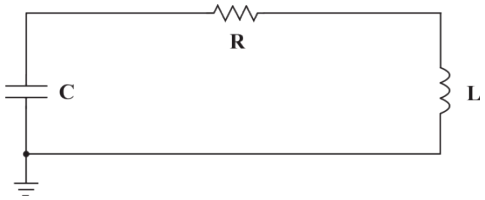

Figure 3. Schematics of an oscillating circuit with losses

Applying the statements b) to d) of the proposed approach, one can write the equations (11). (12) and (13) that describe the circuit in Figure 3:

$$u_L(t) = u_C(t) - Ri(t) \tag{11}$$

$$u_C(t + dt) = u_C(t) - \frac{i(t)dt}{C} \tag{12}$$

$$i(t + dt) = i(t) + \frac{u_L(t)dt}{L} \tag{13}$$

Equation (11) states the Kirchhoff's voltage law – sum of the voltages in a closed loop equals zero.

Equations (12) and (13) are the two bridges in time from the current time *t* to the time just after the current time, which is *t + dt*.

One can perform the DC analysis at time *t* by (11) and walk from the time *t* to the time *t + dt* by (12) and 13. When (11), (12) and (13) are executed sequentially in a program loop where *t + dt* is changed for *t* in each iteration then the iterative simulation of equations (11), (12) and (13) calculates the transient response of the circuit in Figure 3.

IV. RESULTS

Simulation of the equations (7) and (8), describing the circuit in Figure 1, in is Figure 4. The voltage source

produces alternating voltages of 0 V and 10 V with a period of 10 milliseconds.

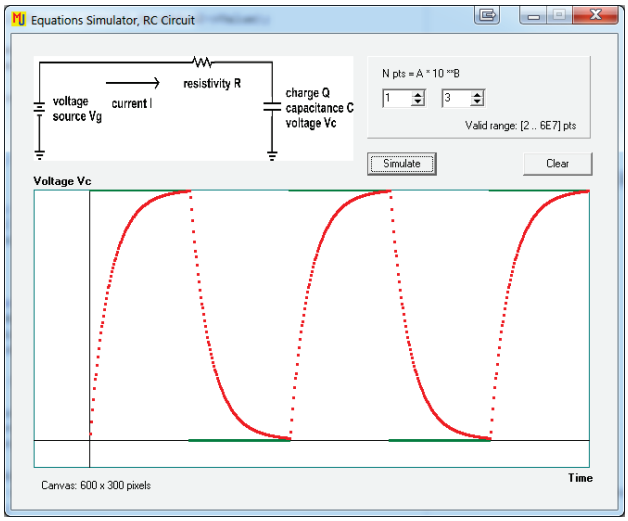

Figure 4. Result of simulating the RC circuit, by the equations (7) and (8)

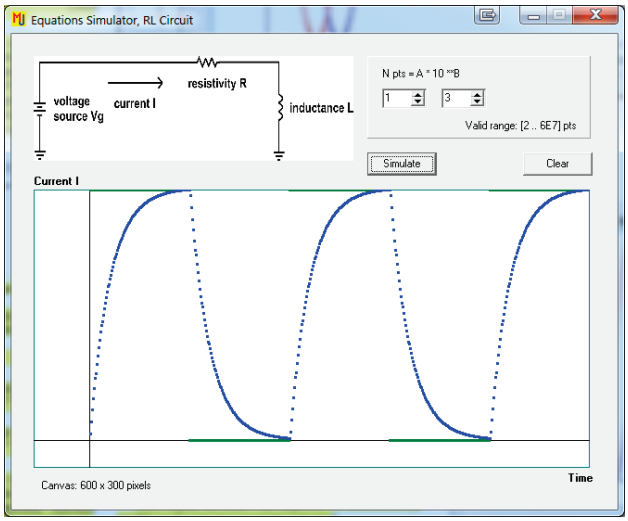

Figure 5. Results of simulating the RL circuit, by the equations (9) in (10)

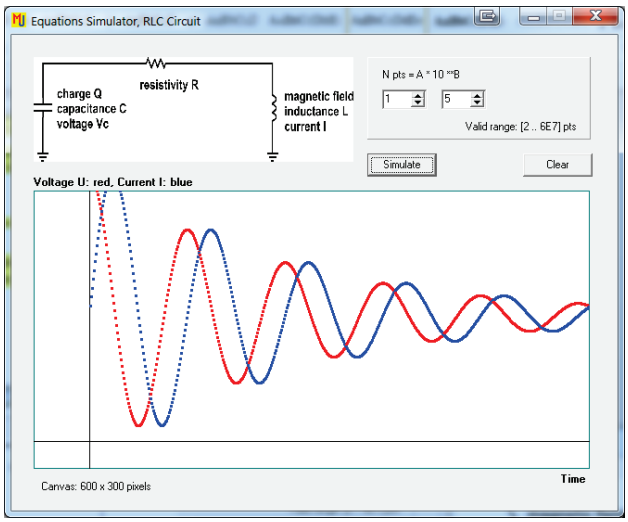

Figure 6. Results of simulating the RLC circuit – an oscillator with losses, by the equations (11), (12) and (13)

The green curve in Figure 4 represents output of the voltage source. The red curve represents the voltage on the capacitor.

Simulation of the equations (9) and (10), describing the circuit in Figure 2, is in Figure 5. The voltage source produces alternating voltages of 0 V and 10 V with a period of 10 milliseconds.

The green curve in Figure 5 represents output of the voltage source. The blue curve represents the current through the inductor.

Simulation of the equations (11), (12) and (13), describing the circuit in Figure 3, is in Figure 6. Initial voltage on the capacitor is 10 V.

The red curve in Figure 6 represents the voltage on the capacitor. The blue curve represents the current through the inductor.

Simulation of the equations (11), (12) and (13), describing the circuit in Figure 3, having resistor $R = 0$ *Ohm*. is in Figure 7. Initial voltage on the capacitor is 10 V.

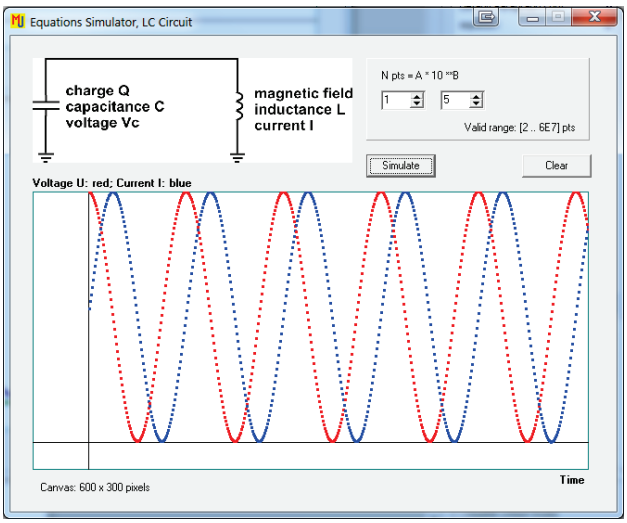

Figure 7. Results of simulating the LC circuit – an oscillator without losses, by the equations (11), (12) in (13)

The red curve in Figure 7 represents the voltage on the capacitor. The blue curve represents the current through the inductor.

V. DISCUSSION

Simulation of the equations (7) and (8), for behavior of the circuit in Figure 1, displayed in Figure 4, shows exactly the same results as one would obtain by breadboarding the circuit in Figure 1.

The same is valid for the combination of the equations (9), (10) and Figures 2 and 5.

The same is valid for the combination of the equations (11), (12), (13) and Figures 3 and 6.

For the obvious reason of not having superconducting wires at room temperature one cannot breadboard the lossless oscillator having the calculated response in Figure 7.

A lossless oscillator is a special case of an oscillator. The theory of electric and mechanical oscillators is widely covered in many books on engineering physics, as in [5].

Simulation of the equations (11), (12), (13) for $R = 0$ *Ohm* is displayed in Figure 7.

Simulating circuit behavior by the simulation of equations can be sensitive to the length of the time interval *dt* between the two consecutive times, namely between *t* and $t + dt$.

The smallest numerically possible *dt* results in rounding errors. The time interval *dt*, that is obnoxiously long, obfuscates the mapping from the equations (1) and (2) to the equations (5) and (6). This phenomenon is illustrated in Figure 8. For more insight, one can download the first version of the equations simulator from the http://www2.arnes.si/~mjenko9/SimEq/SimAll.exe and can experiment with the length of the time interval *dt* between the two consecutive times in the semi continuous simulation.

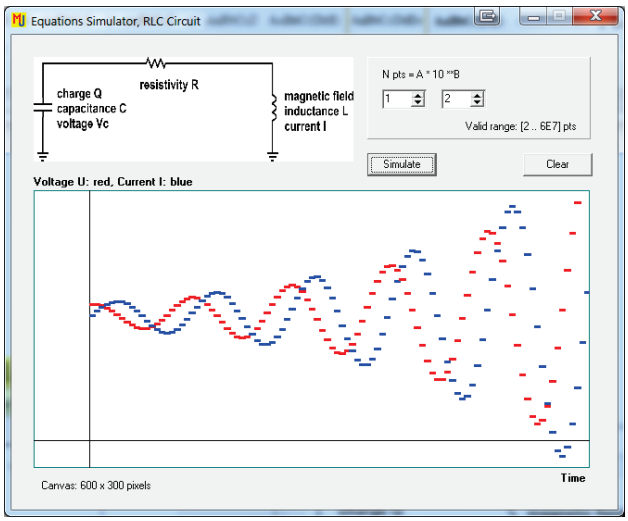

Figure 8. Same set up as in Figure 6, only the time interval *dt* is too long for a valid simulation of an oscillator with losses by the simulation of equations

Both simulations, in Figure 6 and in Figure 8, have length of 25 milliseconds. The iterative loop of equations (11), (12) and (13) is executed one hundred thousand times for the results in Figure 6, and only two hundred times for the results in Figure 8.

While experimenting with the time interval *dt*, one finds that the simulation results for the RLC circuit are identical and correct from five thousand iterations further on. Five microseconds is the longest time interval that still results in the correct results for the particular circuit.

VI. CONLUSION

Validity of the presented concept of simulating the circuit by simulation of equations is confirmed by the results of the test cases.

This approach to simulation gives maximum freedom when simulating and studying circuits. It has potential for study of other physical phenomena. One can study circuits and systems consisting of arbitrary, even time variant elements by the simulation of equations.

***Abstract*—This paper presents a novel and simple simulation method to evaluate the impulse phase response of an oscillator. The technique, based on the linear-time variant (LTV) analysis of oscillators, computes the phase response in the frequency domain. It can be performed by means of periodic steady-state (PSS) and periodic transfer function (PXF) simulations available in commercial simulators (Spectre, Eldo, etc.). This method overwhelms the classical simulation method based on transient analysis and injection of charge pulses along the oscillator period in terms of both speed and precision. The good accuracy of the frequency domain method has been verified in two practical case studies, evaluating the $1/f^3$ phase noise in a classical Van der Pol oscillator and estimating the injection locking range in a ring oscillator-based frequency divider.**

***Index Terms*—oscillator, phase noise, injection locking, impulse sensitivity function, linear time variant analysis, locking range.**

I. Introduction

PHASE noise of VCOs (Voltage Controlled Oscillators) and PLLs (Phase Locked Loops) is still a major issue in the design of wireless communication systems since it limits the maximum achievable data transfer rate [1]. Since bit-rates keep increasing with time, this results in more stringent requirements of the transceiver and a deep insight of phase noise generation mechanism is necessary to perform an optimum design. In the framework of linear time variant (LTV) model, which is the most suitable for circuits with a periodically varying operating point such as oscillators, the impulse sensitivity function (ISF) introduced by Hajimiri and Lee [2], [3] provides a very useful tool for the analysis of the oscillator system dynamics under small signal excitations, such as MOSFET current noise, and thus for evaluating the oscillator phase noise.

The above mentioned sensitivity function is also adopted to analyze injection locking mechanism in oscillators [4], [5]. This phenomenon is observed when an oscillator is perturbed by a weak external signal whose frequency is close enough but not equal to that of the unperturbed oscillator. Under certain conditions, the oscillator frequency is changed and becomes equal to the frequency of the external signal. A part form the theoretical importance, injection locking has been exploited to realize quadrature oscillators or oscillators with finer phase separation [6], [7] and low-power frequency dividers [8].

At the present time, the ISF cannot be directly computed by commercially available circuit simulators, thus requiring ad hoc simulations. The traditional technique, proposed in [2] and adopted by RF designers, is based on the definition of impulse phase response of an oscillator. By means of time-domain transient simulations, current pulses are injected in an oscillator node and the phase response of the system is evaluated. This technique basically trades accuracy off against implementation simplicity and simulation speed. In this paper, a frequency-domain simulation method for the ISF is presented, based on a small-signal analysis, namely the periodic transfer function (PXF) simulation available in Cadence environment [9]. It overwhelms the transient analysis-based method in terms of both accuracy and speed.

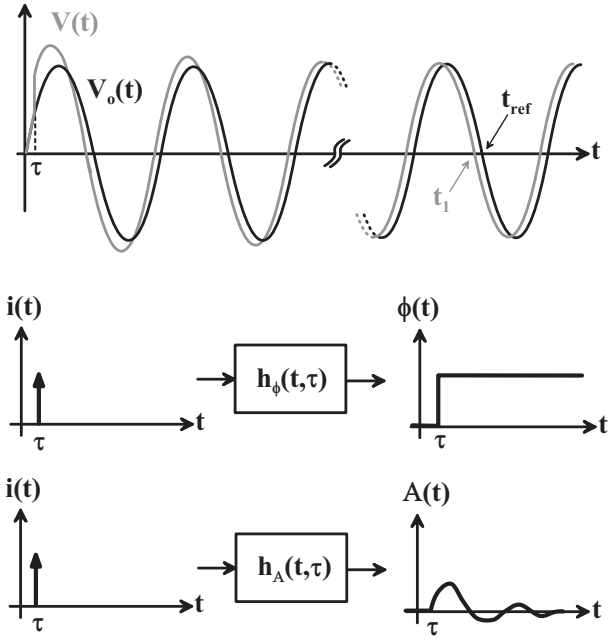

Fig. 1. Impulse responses of oscillation amplitude $h_A(t,\tau)$ and phase $h_{\phi_0}(t,\tau)$. $V_0(t)$ and $V(t)$ refer to unperturbed and perturbed oscillation, respectively.

This paper is organized as follows. Section II briefly reviews some basic concepts of Hajimiri's theory of the impulse sensitivity function. Section III describes the proposed method to simulate the ISF by means of periodic small signal analysis. Section IV shows the comparison between the PXF and transient analysis-based methods in terms of implementation simplicity and simulation speed in a Van der Pol and a ring oscillator, highlighting the advantages of the proposed technique. In Section V the PXF analysis-based method is applied in two practical cases, namely the evaluation of $1/f^3$ phase noise in a LC oscillator and the locking range in a ring VCO-based frequency divider. Finally, conclusions are drawn

in Section VI.

II. Impulse Sensitivity Function

Consider a generic oscillator whose output voltage can be expressed as $V(t)$=$A(t)\cos\left[\omega_0 t + \phi_0(t)\right]$, being $A(t)$ and $\phi_0(t)$ the amplitude and the phase of the oscillator perturbed by electronic noise and ω_0=$\frac{2\pi}{T_0}$ the oscillation frequency. A time-domain analysis can be performed considering that (i) a linear model is valid under the hypothesis of small perturbation (always valid when considering oscillator noise) and (ii) both amplitude and phase of the output voltage are perturbed. Thus, the oscillator acts like a multiple-input multiple-output (MIMO) system, where the inputs are the noise sources while the outputs are the oscillation amplitude $A(t)$ and phase $\phi_0(t)$. It is thus possible to define two different impulse responses for each noise source, $h_A(t,\tau)$ and $h_{\phi_0}(t,\tau)$.

The impulse response associated to the oscillation amplitude $h_A(t,\tau)$ is of little interest since it rapidly fades asymptotically because of the amplitude limitation mechanism due to the transconductor non-linearity. The impulse response of the phase is instead of greater interest. It results in a step function $u(t)$, as visible in Fig. 1, meaning that the phase shift arisen from a single charge pulse is not recovered since the oscillator has no time reference. The height of the step function is highly dependent on the time instant τ of the input impulse. Thus $h_{\phi_0}(t,\tau)$ can be written as $h_{\phi_0}(t,\tau) = h_\phi(\tau)\,u(t-\tau)$, where $h_\phi(\tau)$ is a T_0-periodic function. The perturbed phase of the oscillator output voltage caused by a noisy current $i_n(t)$ applied between two generic nodes can be expressed as:

$$\phi(t) = \int_{-\infty}^{+\infty} h_{\phi_0}(t,\tau)\, i_n(\tau)\, d\tau = \int_{-\infty}^{t} h_\phi(\tau)\, i_n(\tau)\, d\tau. \tag{1}$$

In [2] the impulse sensitivity function is defined as a dimensionless function, $\Gamma(\tau)$, given by $h_\phi(\tau)\cdot q_{max}$, q_{max} being the maximum charge displacement across the capacitor between the nodes. In this paper, we will instead refer to the impulse sensitivity function as $h_\phi(\tau)$. In both cases, being the ISF closely related to the phase impulse response $h_{\phi_0}(t,\tau)$, its definition suggests a method for its simulation, reported in [2]. Perturbing the oscillator with a charge pulse $i_n(t) = q_{inj}\delta(t-\tau)$, $h_\phi(\tau)$ is given by $\frac{\Delta\phi(\tau)}{q_{inj}}$, where $\Delta\phi$ is the asymptotical output phase shift. The required steps for computing $h_\phi(\tau)$ are the following:

1) Run a simulation of the unperturbed oscillator and annotate a time instant t_{ref} when the output voltage crosses an arbitrarily chosen value V_{ref}, once the initial transient has faded. Referring to Fig. 1, V_{ref} has been chosen equal to 0.
2) Apply a short current pulse of area q_{inj} at instant τ at the nodes where the current noise source is applied. If the injected charge produces a phase shift much smaller than 2π, the output voltage will cross V_{ref} at the instant t_1 close to t_{ref} (see Fig. 1).
3) The variation of the oscillation phase is obtained as $\Delta\phi = \omega_0(t_{ref} - t_1)$, resulting in $h_\phi(\tau) = \frac{\Delta\phi}{q_{inj}}$.
4) Sweep the injection time instant τ over one oscillation period computing for each instant the phase shift. The more accuracy is needed, the more transient simulations must be run.

Despite its simplicity, this procedure is time-consuming. In addition, since the injected charge has to be small, the results may be affected by numerical noise.

III. The proposed method

The method proposed in this work derives the oscillator impulse phase response in the frequency domain by means of a PXF (periodic transfer function) analysis available in commercial RF circuit simulators. Let us consider the output voltage of the unperturbed oscillator at the fundamental frequency as $V(t) = A_0\cos\left[\omega_0 t + \phi_0\right]$ and the ISF to be evaluated:

$$h_\phi(t) = \frac{h_0}{2} + \sum_{k=1}^{+\infty} h_k \cos\left(k\omega_0 t + \varphi_k\right), \tag{2}$$

where h_k and φ_k are the magnitude and the phase of the k-th harmonic term, respectively. In (2) h_0 is the DC component of the impulse phase response that can be either a positive or a negative value. In this frame, a small current tone at an offset $-\omega_m$ around the k-th harmonic of the output voltage,

$$i_n(t) = i_n\cos\left[\left(k\omega_0 - \omega_m\right)t\right], \tag{3}$$

causes a phase modulation at ω_m of the output voltage at the fundamental frequency. In fact, from (1), (2) and (3), the corresponding output phase can be approximated by the slow frequency component as:

$$\phi(t) \cong \frac{h_k i_n}{2\omega_m}\sin\left(\omega_m t + \varphi_k\right). \tag{4}$$

Note that only the k-th harmonic term of the ISF contributes to determine the output phase $\phi(t)$. Thus, the output voltage at the fundamental frequency, $V(t) = A_0\cos\left[\omega_0 t + \phi_0 + \phi(t)\right]$, shows two correlated terms at $\omega_0 \pm \omega_m$, that is:

$$\begin{aligned} V(t) \cong\ & A_0\cos\left(\omega_0 t + \phi_0\right) + \\ & -V_k^{PM}\cos\left[\left(\omega_0 - \omega_m\right)t + \Phi_k^-\right] + \\ & +V_k^{PM}\cos\left[\left(\omega_0 + \omega_m\right)t + \Phi_k^+\right], \end{aligned} \tag{5}$$

where $V_k^{PM} = \frac{A_0 h_k i_n}{4\omega_m}$, $\Phi_k^- = \phi_0 - \varphi_k$ and $\Phi_k^+ = \phi_0 + \varphi_k$. Thus, the magnitude and the phase of the harmonic terms of $h_\phi(t)$ can be computed as:

$$h_k = \frac{4\omega_m V_k^{PM}}{A_0 i_n} \tag{6}$$

$$\varphi_k = \Phi_k^+ - \phi_0 \tag{7}$$

In the case of the $h_\phi(t)$ DC component, φ_0 can be either 0 or π. These equations pose the basis of the numerical methodology to derive the ISF function by means of a PXF simulation, which computes the magnitudes $\frac{V_k^{PM}}{i_n}$ and the phases Φ_k^+ of the periodic small-signal transfer function from a single current tone at frequency $k\omega_0 - \omega_m$ to the output voltage at frequency $\omega_0+\omega_m$. The index k is an integer number automatically swept between 0 and K, where K can be limited to 5-6 for sinusoidal oscillators. In the above mentioned equations A_0 and ϕ_0 are the magnitude and the initial phase of the first harmonic of the output voltage, respectively, and

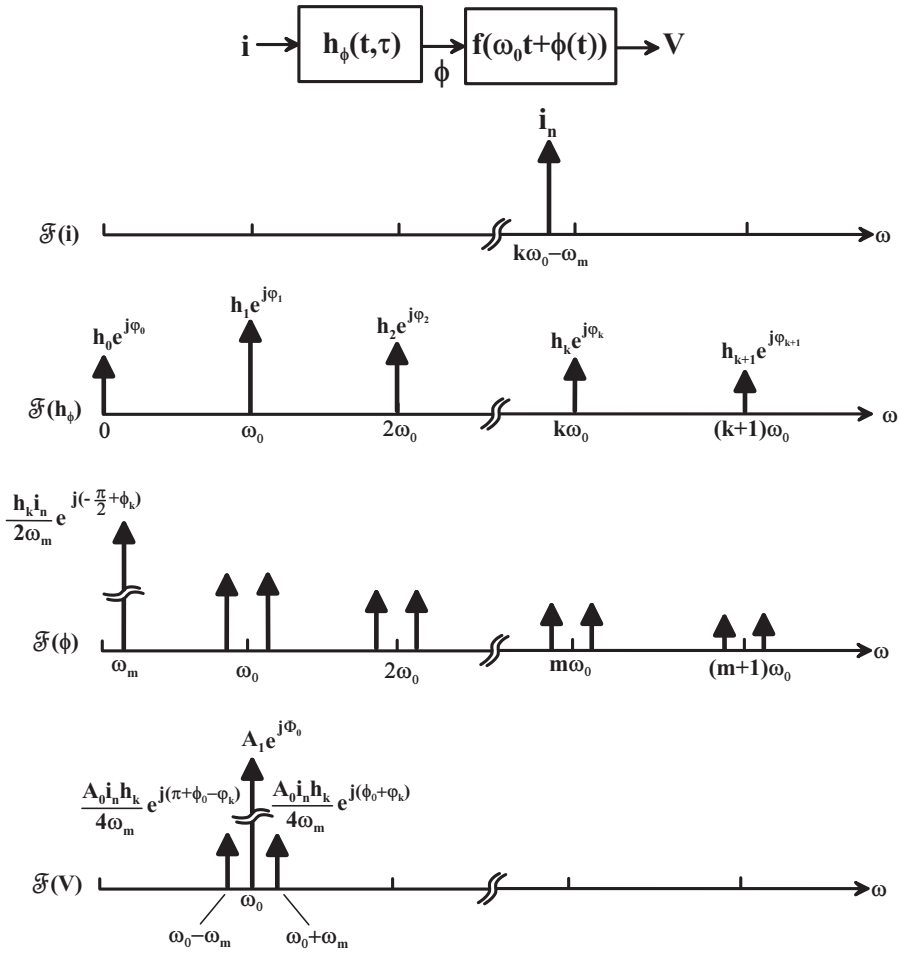

Fig. 2. Spectra of injected current tone, impulse sensitivity function, output phase and output voltage.

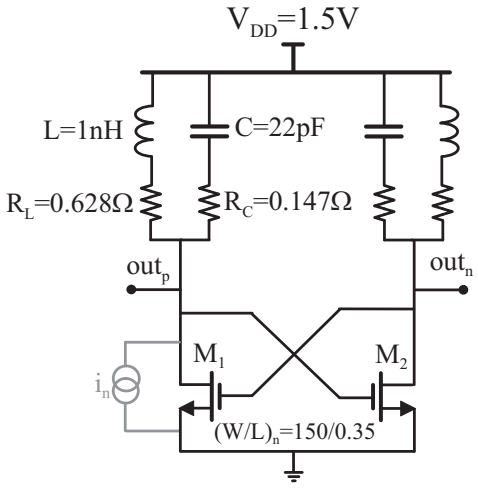

Fig. 3. The simulated Van der Pol oscillator.

can be estimated through a single PSS (Periodic Steady State) simulation. Finally, note that the PXF simulation is a linear analysis; the circuit is linearized around the time-varying operating point, thus avoiding the problem of large injected signal occurring when performing transient analysis. Fig. 2 shows the spectra of the injected current tone $i_n(t)$, $h_\phi(t)$, output phase $\phi(t)$ and modulated output voltage $V(t)$.

IV. Simulation results

The computation of the ISF is greatly simplified using a simulation environment that supports scripting, such as Cadence Open Command Environment for Analysis (Ocean). However, while with the proposed technique the results can be achieved in a completely automatic way, the transient analysis-based method requires a manual calibration before being performed. In particular, the amount of charge injected into the circuit with each single pulse must be properly chosen in order to be sufficiently small to assure a linear relationship between charge and phase and sufficiently large to make the simulator numerical error negligible. As a practical case, the ISF has been simulated with both the Hajimiri's and the proposed method for two oscillator topologies, namely a Van der Pol and a ring oscillator shown in Fig. 3 and Fig. 4, respectively. Both oscillators are designed in a 0.35-μm CMOS technology and run at 1-GHz frequency.

In the Van der Pol oscillator the ISF is simulated for a current noise source connected between one of the output and ground, as shown in Fig. 3. Fig. 5 shows the comparison between the results obtained with the PXF and transient analysis-based methods, the latter being performed with three different values of the ratio between the injected charge and the maximum charge stored in the tank capacitor. In particular, a perfect matching between the results of the two methods is achieved for an injected charge ratio equal to 10^{-2}. As this

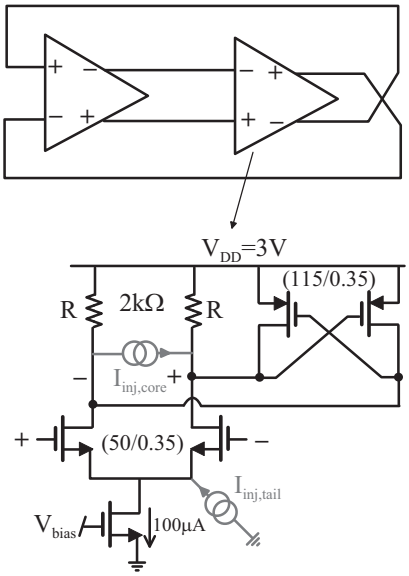

Fig. 4. The simulated ring oscillator.

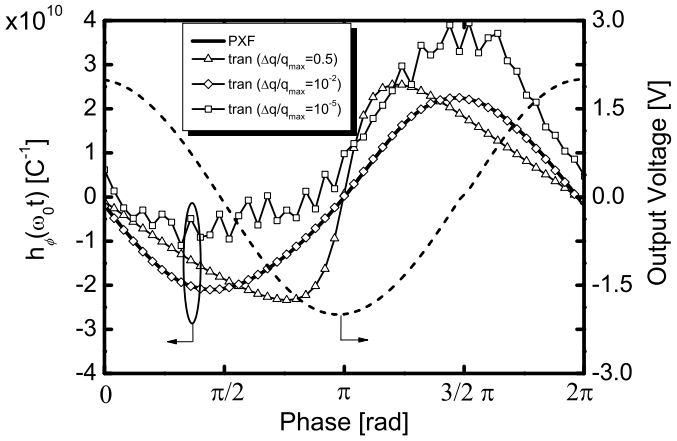

Fig. 5. Simulated ISF of the Van der Pol oscillator in Fig. 3 using the proposed PXF and transient analysis-based methods.

ratio is raised by two order of magnitude, the resulting ISF is distorted, while, as the ratio is lowered by three orders of magnitude, the resulting waveform is affected by numerical error.

In the ring oscillator of Fig. 4 the ISF has been simulated for the tail current noise source and for a noise source across the differential output, namely $I_{inj,tail}$ and $I_{inj,core}$. The results, plotted in Fig. 6, suggest a perfect matching between the ISF waveforms obtained with the two methods.

Finally, Table 1 reports a comparison between the simulation times for the two methods in both oscillators. The simulations have been performed in the Cadence Ocean environment with a 3-GHz Pentium Xeon featuring a 4-Gbyte main memory. A total of N=50 time instants over one oscillation period have been simulated by means of transient analyses.

TABLE I
ISF SIMULATION TIME

Topology	Simulation Time (TRAN)	Simulation Time (PXF)
Van der Pol	16m 4s	2m 8s
Ring	11m 50s	1m 45s

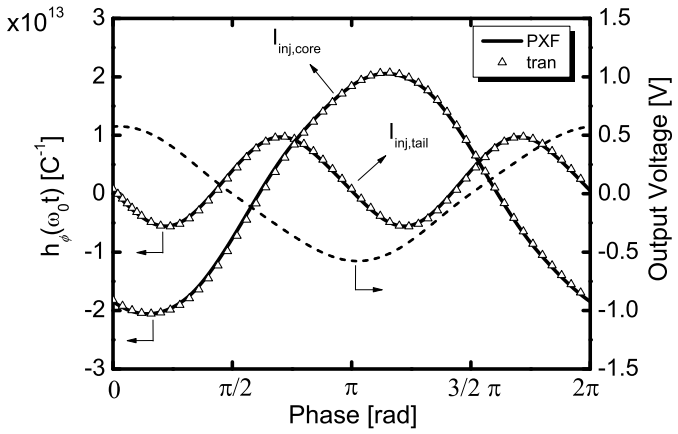

Fig. 6. Simulated ISFs of the ring oscillator in Fig. 4 using the proposed and transient analysis-based simulation method.

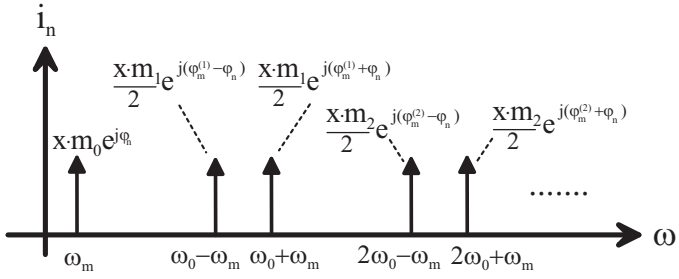

Fig. 7. Cyclostationary noise tones resulting from a slow frequency current tone, $x(t) = x \cdot \cos(\omega_m t + \varphi_n)$.

The computation time with the transient analysis-based simulation method is approximately 50 times larger than adopting the proposed simulation technique.

V. CASE STUDIES

In this section the proposed method for computing the impulse sensitivity function and its harmonic terms is validated in two practical cases.

A. Evaluation of the $1/f^3$ phase noise in a Van der Pol oscillator

Consider the Van der Pol oscillator in Fig. 3. Flicker noise due to active elements is up-converted around the carrier giving rise to $1/f^3$ phase noise. Since the circuit is symmetric, this close-in phase noise can be evaluated considering that the two transistors feature the same contribution. A simple model equation for the $1/f$ noise is provided by [10] and adopted by the SPICE2 flicker noise model. According to it, the power noise spectral density may be written as:

$$S_I(\omega) = \frac{K_F |I_{DS}|^\alpha}{C'_{ox} L^2_{MOS}} \frac{2\pi}{\omega}, \tag{8}$$

where K_F is a process dependent constant, I_{DS} the transistor channel current, L_{MOS} the MOS channel length with the exponent α ranging between 1 and 2. Since I_{DS} is not a constant but a periodic function varying with time, the noise process becomes cyclostationary. Such processes can be described starting from a stationary noise and then considering the intermixing of the noise components arising from the large variation of the device current [11]. Referring to the flicker

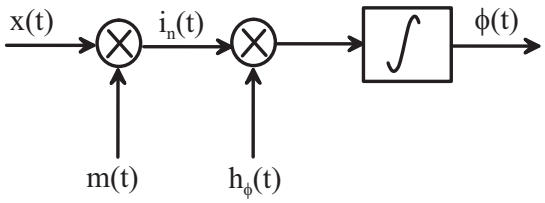

Fig. 8. Block diagram describing the generation of the $1/f^3$ phase noise from the modulation through $m(t)$ of a stationary source $x(t)$.

noise model given by (8), the noise components are considered as generated by the product [11]:

$$i_n(t) = x(t) \cdot m(t), \tag{9}$$

where

$$x(t) = x \cdot \cos(\omega_m t + \varphi_n) \tag{10}$$

is a noise tone with frequency ω_m and phase φ_n randomly distributed over the $0 - 2\pi$ interval, while the amplitude x is chosen to account for the stationary part of the unilateral power spectral density:

$$S_x(\omega) = \frac{K_F}{C'_{ox} L^2_{MOS}} \frac{2\pi}{\omega}. \tag{11}$$

The modulating periodic function is instead given by:

$$m(t) = |I_{DS}(t)|^{\alpha/2}. \tag{12}$$

Being $I_{DS}(t)$ a periodic function, $m(t)$ can be expanded in a Fourier series as:

$$m(t) = \frac{m_0}{2} + \sum_{l=1}^{+\infty} m_l \cos\left(l\omega_0 t + \varphi_m^{(l)}\right) \tag{13}$$

with Eulerian components given by $m_l e^{j\varphi_m^{(l)}}$. Note that the product $m(t) \cdot x(t)$ generates correlated noise components i_n at offsets $k\omega_0 \pm \omega_m$, as shown in Fig. 7. These correlated noise components translate via the $h_\phi(t)$ to phase noise. This process is schematically depicted in Fig. 8. From (1) and (9), the contribution to the output phase arising from the low-frequency tone $x(t)$ can be therefore written as:

$$\phi(t) = \int_{-\infty}^{t} h_\phi(\tau)\, m(\tau)\, x(\tau)\, d\tau, \tag{14}$$

where $h_\phi(t)$ is referred to a current noise generator connected between one of the output and ground. Since the Fourier decomposition also holds for the ISF (see (2)), the output phase $\phi(t)$ becomes:

$$\phi(t) = \int_{-\infty}^{t} \left[\frac{h_0}{2} + \sum_{l=1}^{+\infty} h_l \cos\left(l\omega_0\tau + \varphi_h^{(l)}\right)\right] \cdot \cdot \left[\frac{m_0}{2} + \sum_{k=1}^{+\infty} m_k \cos\left(k\omega_0\tau + \varphi_m^{(k)}\right)\right] x(\tau) d\tau. \tag{15}$$

In the above equation only the slow varying terms, arising from the multiplication of Fourier components with the same index, are not suppressed by the integral operator. Thus, the phase $\phi(t)$ can be approximated as:

$$\phi(t) \cong \frac{x}{2\omega_m}\left[\frac{1}{2}h_0 m_0 + \sum_{k=1}^{+\infty} h_k m_k \cos\left(\varphi_h^{(k)} - \varphi_m^{(k)}\right)\right] \cdot \cdot \sin(\omega_m t + \varphi_n). \tag{16}$$

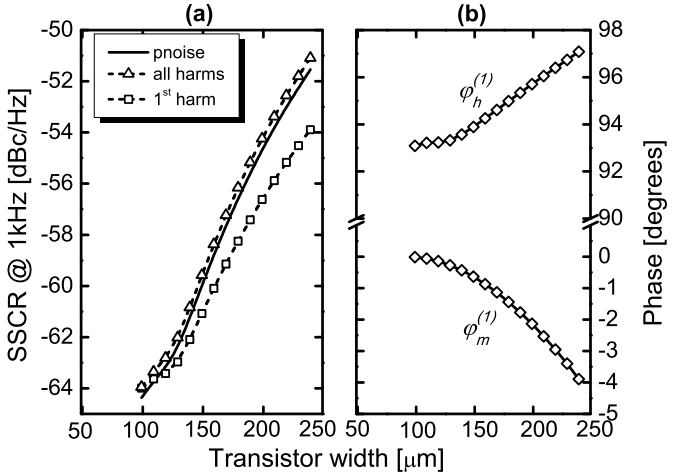

Fig. 9. $1/f^3$ phase noise at 1-kHz offset (a) and phase of the first harmonic of $h_\phi(t)$ and $m(t)$ (b). Solid line in (a) refers to the simulated phase noise while symbols correspond to the estimation given by (19) (squares refer to the first harmonic contribution in (19)).

The amplitude of this phase modulation at frequency ω_m results:

$$\Delta\phi \cong \frac{x}{2\omega_m}\left[\frac{1}{2}h_0 m_0 + \sum_{k=1}^{+\infty} h_k m_k \cos\left(\varphi_h^{(k)} - \varphi_m^{(k)}\right)\right], \tag{17}$$

and is linked to the single sideband to carrier ratio (SSCR or $\mathcal{L}$) [2] being:

$$\mathcal{L}(\omega_m) = SSCR(\omega_m) = (\Delta\phi/2)^2 \tag{18}$$

From (11), (17) and (18), $1/f^3$ phase noise at ω_m results:

$$\mathcal{L}(\omega_m) \cong \frac{2S_x(\omega_m)}{8\omega_m^2}\left[\frac{h_0 m_0}{2} + \sum_{k=1}^{+\infty} h_k m_k \cos\left(\varphi_k^{(k)} - \varphi_m^{(k)}\right)\right]^2, \tag{19}$$

where the factor of 2 takes into account that the flicker noise of the two transistors is uncorrelated. Thus, the $1/f^3$ phase noise computation requires a precise knowledge of the Fourier coefficients of both $h_\phi(t)$ and $m(t)$, the latter being achievable by means of a PSS analysis. Fig. 9(a) shows the simulated $1/f^3$ phase noise at 1-kHz offset (solid line) and the estimation given by (19) (triangles) varying the transistor width from $100\mu m$ to $250\mu m$. The term with index k=1 in (19) is the dominant (see Fig. 9(a), squares). In fact, for growing transistor widths, the two phases $\varphi_h^{(1)}$ and $\varphi_m^{(1)}$ rapidly depart from $90°$ and $0°$, respectively (see Fig. 9(b)), causing an increase of the term $\cos\left(\varphi_h^{(1)} - \varphi_m^{(1)}\right)$ in (19). This behavior can be related to an increase of transconductor non-linearity which grows with the transistor width [12].

B. Injection locking range in a ring oscillator

In this section we will demonstrate how the locking range of a generic oscillator perturbed by a weak injected signal around the *k*-th harmonic of the fundamental frequency can be easily related to the magnitude of the impulse phase response and thus simply evaluated by means of the proposed simulation method.

Let us suppose that the oscillator is perturbed by a purely harmonic signal injected in a generic node,

$$I_{inj}(t) = i_{inj} \cdot cos(\omega_{inj} t + \theta), \tag{20}$$

and the impulse phase response associated to the node can be expanded in a Fourier series as in (2). When ω_{inj} falls in the frequency range centered around $m\omega_0$, referred to as the locking range (LR), a synchronization effect of order $1:m$ (i.e., the injection locking) takes place if the oscillation frequency ω_0 varies till to be locked to the value $\omega = \frac{\omega_{inj}}{m}$. In the case of locking or pulling of the oscillation frequency, (1) is no longer valid since the Hajimiri's linear model is not able to capture those phenomena. However, in the case of weak injected signal, the effect can be reduced to a time shift deviation of the impulse response [4] and the differential equation describing the evolving of the oscillator phase can be written as:

$$\frac{d\phi(t)}{dt} = h_\phi\left(\omega_0 t + \phi(t)\right) \cdot b(t), \tag{21}$$

$b(t)$ being the perturbation of the free-running oscillator, i.e. $b(t) = i_{inj} \cdot cos\left(\omega_{inj} t + \theta\right)$. In the case of $\omega_{inj} \cong \omega_0$, the output voltage once the oscillator is locked results:

$$V(t) = A_0 cos\left(\omega_0 t + \phi_0 + \phi\left(t\right)\right) = A_0 cos\left(\omega_{inj} t + \phi_1\right), \tag{22}$$

being ϕ_0 and ϕ_1 the initial phase of the oscillator before and after the locking, respectively. Thus, the phase $\phi(t)$ that solves (21) is:

$$\phi\left(t\right) = \left(\omega_{inj} - \omega_0\right) t + \overline{\phi}, \tag{23}$$

with $\overline{\phi} = \phi_1 - \phi_0$. Substituting (23) into (21), it results:

$$\omega_{inj} - \omega_0 = \frac{h_1 i_{inj}}{2} cos\left(\varphi_1 - \varphi_{inj} + \overline{\phi}\right), \tag{24}$$

Sweeping $\overline{\phi}$ over all possible real values and observing that $|cos\left(\cdot\right)| \leq 1$, the locking range results:

$$\frac{i_{inj} h_1}{2} \geq |\omega_{inj} - \omega_0|. \tag{25}$$

In the general case of injected tone close to a multiple of the fundamental frequency, i.e. $\omega_{inj} \cong m\omega_0$, (25) becomes:

$$\frac{m \cdot i_{inj} h_m}{2} \geq |\omega_{inj} - m\omega_0|, \tag{26}$$

which reduces to (24) for $m = 1$. Thus, in the case of purely weak harmonic injected signal the synchronization of order $1:m$ is completely determined by the magnitude of the *m*-th Fourier component of the impulse phase response. In this framework, the proposed method to compute the harmonic components of $h_\phi\left(t\right)$ is very helpful to determine the lock-range in the case of injection of current tones in free-running oscillators. As numerical application, we analyze the lock-range in the 1-GHz ring oscillator of Fig. 4 injecting a current tone either across the outputs of the second stage and at the tail node of the differential pair. In the first case, the tone is injected close to the oscillation frequency while in the latter the injection frequency was chosen around the second harmonic. The lock-range obtained by means of transient simulations performed varying the injected current tone amplitude are compared with the results given by (26) in Fig. 10. Thus, simulating by means of the PXF analysis-based method the magnitude of the first and the second Fourier component for the two generators $I_{inj,core}$ and $I_{inj,tail}$ in Fig. 4, respectively, the lock-range can be predicted very easily by means of (26).

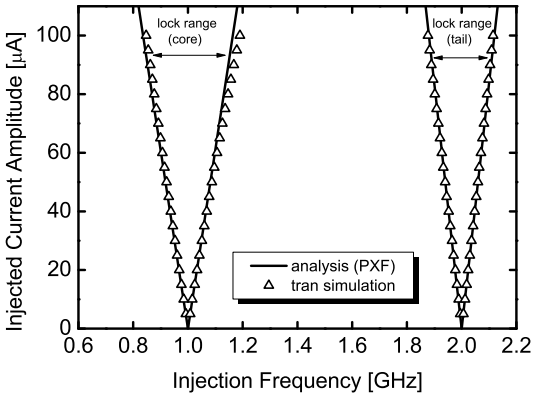

Fig. 10. Lock-range in case of injection of a current tone across the differential output and at the tail node of the ring oscillator in Fig. 4. Symbols refer to transient simulations performed varying for a given frequency the tone amplitude, while solid lines refer to analysis result in (26). The magnitudes h_1=20.6 $\cdot$ $10^{12}C^{-1}$ and h_2=7.5 $\cdot$ $10^{12}C^{-1}$ for the ISFs evaluated at the differential output and at the tail node, respectively, have been computed by means of the PXF analysis-based simulation method.

VI. Conclusions

In this work a fast and accurate simulation method based on PXF analysis for the impulse phase response in oscillators has been presented. The proposed technique overwhelms the traditional simulation method based on transient analysis in terms of both computation time and accuracy. In particular, the method is helpful every time the magnitude and phase of each ISF component is of interest.

***Abstract*—Transient simulations of electronic circuits in the time domain can be one of the most complex tasks that engineers encounter in the field of electronics and microelectronics due to two main problems: slow speed of SPICE transistor level circuit simulations and limited accuracy of classic techniques for improving speed of circuit simulations. The black-box approach to behavioural modelling of electronic circuits, although very challenging, is particularly interesting due to possibility of fast and accurate simulations and that is the reason why black-box modelling techniques are gaining more and more attention in industry and academic community. The goal of this professional paper is to give a brief overview of the topic, identify current state-of-the-art and give suggestions for the future research in the area of black-box behavioural modelling of electronic circuits in the time-domain.**

I. Introduction

Electronic circuits containing many transistors, if simulated in time-domain using SPICE simulators, contain a very large number of nonlinear equations to be solved. Such a task can be difficult, in terms of simulation time and memory, for typical computer workstations available to most designers [1]. Even modern simulation algorithms such as harmonic balance [2] and transient envelope analysis [3] do not solve this problem completely [1], although they are more efficient than traditional methods used by time-domain SPICE-like simulators.

Today, the multi million or billion transistors in microprocessors or high level DSP integrated circuits simply can not be designed at the transistor level of circuit description [1] because the number of nonlinear functions to solve simultaneously is too large for existing circuit simulators. The design of the circuits of such complexity is heavily based on behavioural descriptions of the circuit blocks used in the designs. In general, behavioral modelling tries to describe circuit, subsystem or system based on recorded responses to well-selected excitation signals. Behavioural modelling has become a critical step in designs of large circuit systems.

Black box is a technical term for a device, circuit or a system that is observed in terms of its input, output or transfer characteristics without any knowledge of its internal workings. Black-box modelling usually refers to behavioural modelling of such devices, circuits or systems.

The black-box approach to behavioural modelling, although very challenging, is particularly interesting due to its broad spectrum of possible applications and fast simulation speed. One of the advantages of black-box models is that they can be derived from both measurements and simulations. The measured circuit that can be modelled in the behavioural way, is probably the most accurate representation of this circuit because it includes all parasitic effects (from packaging, bonding, PCB and other sources) which could have been overlooked in SPICE simulations. In the simulation based approach, the circuit simulator is used as a virtual instrument to generate needed data to build a behavioural model. The behavioural modelling methods presented in this work are generally targeted and applicable to both simulation-based and measurement-based cases.

Another advantage of black-box modelling is fast model development requiring much less time than classic physical based modeling that usually takes years to develop.

Black-box modelling is especially difficult at high frequencies. At high frequencies, a behavioural model has to be able to directly or indirectly describe the influence of the circuit parasitics (which are, in general, difficult to extract and model). The behavioural modelling techniques that can accomplish that are especially sought after. There is especially big interest for suitable behavioural models in the wireless communications market, due to its commercial significance [1].

For linear systems, broadband S-parameters can provide an essentially good black-box, measurement based, behavioural model of the component [1] (with obvious limitations regarding frequency range, interpolation issues, noise, causality constraints and other). The linear circuit can therefore, be adequately replaced by S-parameter simulation block (if the mentioned limitations are observed, understood and taken into account). One should also note that circuit terminations (loads) have no impact on the modelling process of the linear circuit [4] while when dealing with nonlinear circuits, the choice of terminations chosen in the training process, directly affects the quality of the model [4]. Unfortunately, nonlinear systems and circuits are more common than linear and are much harder to model. There is no consensus how nonlinear systems should be modelled. The main reason for that is the fact that there are so many types of nonlinear systems

with extremely complex dynamical behaviour that is far from being exhaustively investigated or understood [5]. Nonlinear modelling methods, in general, are highly interdisciplinary, from (device) physics to mathematics and computer science. In this paper, we will focus on black-box solutions based on universal approximators.

This work consists of five sections. The first section presents the background, motivation, scope and outline of this work. The section II presents the typical framework for black-box modelling of electronic circuits. The section III presents typical challenges and problems of black-box modelling and gives suggestions how to solve them. Finally, the conclusions are given in section IV.

II. Framework for modelling of integrated circuits

In this section, the framework for behavioural modelling of integrated electronic circuits is presented. The framework facilitates easier creation of black-box models that can be integrated in the modern circuit simulators.

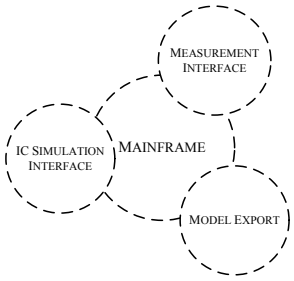

Fig. 1. Basic schematic of the modelling framework.

Figure 1 presents the basic schema of the black-box modelling framework. The basic parts of the framework are:

- Mainframe - this is the main part of the framework. The mainframe controls all parts of the framework. This part contains core black-box modelling procedures and methods.
- Measurement interface - if the modelling is based on measurements, then we need an interface to the measurement data.
- IC simulation interface - there are two main reasons why we need an interface to the modern IC simulators. First, if the modelling is based on simulations, we need an interface to them. Second, we need an interface to the simulator to test the model.
- Model export module - model must be exported to the format suitable for the use in most modern circuit simulators. The good choice for export format is using Verilog-A(MS) or VHDL-A(MS) because it frees the model developer from handling the simulator interface. When implementing models in Verilog-A and VHDL-A, one does not need to be concerned with circuit simulator details. Also, they are considerably simpler then implementations of models in C language where one has to worry about symbolic partial derivatives of the currents and charges in a compact model and determine the proper insertion of these values into the Jacobian matrix for Newtons method [6].

Figure 2 presents the mainframe part of the framework. The basic parts of the mainframe are:

- Data acquisition - this part connects to either the IC simulator or measurement setup (as shown in Figure 1). The data acquisition part includes selection of the excitation signals and acquirement of the training data. The excitation signals have to be well selected in order to capture the full behaviour (or just behaviour of interest) of the modelled system, circuit or device. The excitation signals should cover frequency range of interest.
- Selection of the input-output variables - this step performs selection of the model inputs and outputs. This stage is interconnected with the data acquisition stage.
- Data processing - in this stage, the data from the last step is processed. Several steps are applied, e.g. splitting data in the training, validation and testing data sets, normalisation, scaling, adding delay, differentiating, etc.
- Selection of the model type - e.g. two-stage model such as in [7], [8].
- Selection of the modelling method - several types of current state-of-the art behavioural models are briefly described and discussed in section III-A1. this stage interacts with data processing stage because different modelling methods might require different preprocessing of the model inputs and outputs.
- Selection of the modelling parameters - each modelling method (selected in the previous step), has its own set of parameters which have to be carefully selected. This stage can interact with core modelling stage in an iterative way, to perform an optimisation of the modelling parameters.
- Core modelling stage - this is the part where actual modelling is done.
- Evaluation of the model - finally the model is evaluated.

As arrows in Figure 2 point out, the stages can be recursive and iterative, e.g. if the model accuracy is not satisfactory, another model type should be selected and the process repeated.

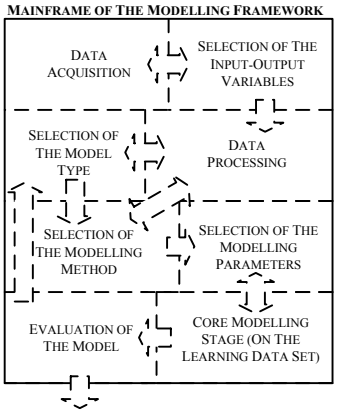

Fig. 2. Modelling framework.

III. Challenges and possible solutions

Several aspects make modelling of the electronic circuits especially difficult:

- Large number and wide choice of passive and particularly active components in case of integrated circuits, passive components include a variety of transmission line structures, resistors, capacitors, inductors and other structures. Furthermore, there is a vast number of active components, e.g. semiconductor devices like MOSFET (Metal-Oxide-Semiconductor Field-Effect Transistor), MESFET (Metal Semiconductor Field-Effect Transistor), BJT (Bipolar Junction Transistor), HBT (Heterojunction Bipolar Transistor), HEMT (High Electron Mobility Transistor) and many other. The modelling process of each of these components is a complex task and therefore, it is even more complex to model circuits that consist of many such components.
- High nonlinearity of active components - there is a broad spectrum of active component types, especially semiconductor transistors and their models (just to name a few: BSIM (Berkeley Short-channel IGFET Model), EKV (Enz, Krummenacher and Vittoz transistor model), PSP (Penn State Phillips transistor model), HICUM (HIgh Current Model), MEXTRAM (Most EXquisite TRAnsistor Model) and many more). None of these models can be adopted to full gamma of transistors, mainly because the behaviour of transistors is highly nonlinear and dynamic and highly dependent on the transistor type and technology it is built in.
- It is often found that both digital and analog circuits are placed on the same die, e.g. it is very common to find systems with embedded digital, analog and radio frequency RF/microwave blocks in a single die with a mixed technology [9]. The Domenech-Asensi et al. in [9] accent that such complex circuits impose to reconsider and replace traditional design methods.
- Black-box modelling is especially difficult at high frequencies. At high frequencies, a behavioural model has to be able to directly or indirectly describe the influence of the circuit parasitics (which are, in general, difficult to extract and model). The behavioural modelling techniques that can accomplish that are especially sought after. There is especially big interest for suitable behavioural models in a wireless communications market, due to its commercial significance [1].
- Circuit terminations (loads) have no impact on the modelling process of the linear circuit [4] while when dealing with nonlinear circuits, the choice of terminations chosen in the training process, directly affects the quality of the model [4].
- There are several constraints on the model which are difficult to satisfy:
  - The models have to be accurate - in order to be practically useful, the models have to be accurate enough. The demand for accuracy varies from application to application and usually conflicts with simulation speed of the model.
  - The models have to simulate fast (especially at the system level) so that IC and system designers can use them. Model development is based on finding a good compromise between accuracy and complexity. Higher complexity usually implies lower simulation speed. The optimal tradeoff between those two parameters depends on the particular application and therefore, it is very hard to define general guidelines.
  - The model should be effectively implementable in modern integrated circuit simulation tools - if the models are not includable into the standard simulation environment, they are practically useless.
  - The models have to be stable and robust to be usable.
  - Extraction principle of the model should be simple enough to be implementable and usable.

A. Selection of the appropriate approximation method

The core of the presented black-box modelling framework is the function approximation method used for nonlinear modelling. This is the most important and most complex part of the framework. Selection of the appropriate approximation method depends on two basic factors:

- Signal complexity - electronic circuits with higher complexity will require usage of approximation techniques that exhibit high accuracy (i.e. low training and testing error) and have excellent generalisation[1] properties.
- Number of IC pins - the higher number of IC pins that we would like to model, the higher dimensionality of the problem is. The higher dimensionality increases susceptibility to the curse-of-dimensionality[2].

Several requirements exist for the function approximation method to be applicable to black-box modelling of electronic circuits:

- the method should be implementable in the modern electronic circuit simulators;
- simulation of models must be fast and therefore, the method should generate small and simple models;
- it is necessary that the methods can handle the case when the model output is connected to its input;
- the method should be applicable to the time domain modelling;
- the method should enable adjustment of compromise between accuracy and speed of simulations;
- the method must be efficient even when modelling large sets of data (as this is often the case when modelling electronic circuits).

The selection of the function approximation method can be made based on the overview of the current state-of-the-art.

[1] A method is said to generalise well when the input-output mapping computed by the method is adequately correct even for the test data (i.e. data never used in training or validation of the method).

[2] Term curse-of-dimensionality in the field of machine learning usually refers to the problem of an exponential growth in model complexity needed to adequately model the observed data as a consequence of an increase in (input or output) dimensionality [10].

1) Overview of the "state-of-the-art" function approximation methods for black-box modelling of electronic circuits: As mentioned in the introduction, there is no consensus how nonlinear systems should be modelled. In this section we will give an overview of the current state-of-the-art function approximation methods for black-box nonlinear modelling of electronic circuits. In recent years, several quite different techniques gained popularity:

- Volterra methods - Italian mathematician Vito Volterra (1860-1940) developed the branch of mathematics known as functional analysis. Inspired by his work, Norbert Wiener hypothesised that time-invariant nonlinear systems could be modelled by series of Volterra functionals, provided that the nonlinearities are not too strong. With the recent interest in behavioural modelling of nonlinear systems, the application of Volterra series is once again interesting. Their main advantage is that they have a firm theoretical background, while the main disadvantage is that they are limited to weakly-nonlinear systems [1]. Good theoretical background about Volterra methods can be found in [11]. In [1] more practical introduction to Volterra methods for behavioural modelling can be found. This work focuses on behavioural modelling that is not limited to modelling of weak nonlinearities and therefore, this method will not be investigated further;
- black box piecewise linear (PWL) approximation - Feo and Storace in [12] described a black-box identification method based on state space reconstruction and PWL approximation, and applied it to some several dynamical systems (two topological normal forms and the Colpitts oscillator). It should be noted that PWL methods used in behavioural modelling are usually white-box methods [5]. Although the presented results were promising, this method has the same issues as other PWL methods (as described in [5]), e.g. potential exponential explosion in the number of regions as the dimension of the state space grows, inability to capture higher order derivative information, problems in case of insufficient training waveforms;
- artificial neural networks - ANNs were shown to be suitable as the function approximation method for blackbox modelling of electronic circuits and devices. The first example of application of ANN in electronics was the modelling of the output characteristics of a MOS transistor by Litovski et al. in [13] (where output characteristics are approximated by a feed-forward three layer ANN). Since then, many authors have reported and further developed use of ANNs in the field of behavioural modelling of electronic circuits and devices [8], [14]–[23], but some issues and problems still remain such as the problems with automatic selection of the ANN parameters (such as (usually random) initialisation of ANN weights that leads to unequal quality of the model when the training is repeated, difficult choice of the number of hidden neurons and ANN topology etc.), stability (in case of recurrent ANNs), generalisation properties (and adherent problems with overfitting) and robustness. These problems can lead to difficult automation of building the ANN based electronic circuit models;
- support vector regression machines - Ceperic and Baric in [7] report first usage of support vector regression machines for modelling of analog circuits. Support vector machines, due to their favourable properties, can show better performance in modelling electronic circuits and devices, when compared to ANNs.

Support vector machines: Support vector machines (SVM) have recently generated a great interest in the machine learning community due to its excellent generalization performance in a wide variety of learning problems. Some of the additional reasons for wide use of SVM are: they come with theoretical guarantees about their performance, are less affected by local minima and curse-of-dimensionality. The decreased effect of the curse-of-dimensionality facilitates easier creation of multiport circuit models. From better generalization of the SVMs it can be concluded that a smaller number of training points is needed for the same accuracy of the model.

Ceperic and Baric in [7] report first usage of support vector regression machines for modelling of analog circuits. Guo et al. in [24] present a combination of the conventional equivalent circuit model and support vector machine regression for modelling of MESFET devices. Karsmakers et al. in [25] report usage of least-squares support vector machines in modelling of electronic devices.

There are two main drawbacks of SVMs for black-box modelling of electronic circuits in the time domain. First is the fact that the number of support vectors can be large (if the training data set is large and if the SVM parameters (e.g. width of ε-tube) are not carefully selected). The second is that SVM are not inherently suitable for modelling where feedbacks are needed. The two mentioned drawbacks are addressed by Ceperic and Baric in [26] (Time-Domain Active Learning Support Vector Regression, TASVR) yielding sparse SVM models with feedbacks. The TASVR is applied to modelling of electronic circuits in patent application [27].

B. Model inputs and outputs

In order to obtain the training data necessary to build the black-box model, an input signal must be applied to electronic circuit and the input-output space should be adequately sampled (w.r.t. desired frequency range of operation and Nyquist-Shannon sampling theorem). In [7], [28], a frequency modulated (chirp) signal is used to extract the modelling (training) data. An appropriate frequency range for chirp signal must be selected based on the electronic circuit being modelled. In [29], a pulse stimulus is used. Pulse stimulus can have broad frequency content and therefore, can be suitable for certain types of electronic circuits. In [30], data is extracted in accordance with the extraction-space protocol [30] but this approach was not intended for time-domain modelling.

The best choice of stimuli to extract the data actually depends on the electronic circuit type, desired frequency range of

operation and required accuracy of the model. Good approach is to mix generic stimuli (e.g. frequency modulated sinusoid) with typical stimuli for the electronic circuit being modelled. In general, the training data must cover adequately the range of electronic circuit behaviour that is desired to be modelled. The adequate training data enables good generalisation of the model (if used with function approximation methods having generalisation properties).

The simplest way of selecting appropriate input variables is by experience or trial and error. One can select input variables also according to some statistical method, e.g. by using correlation coefficients between input and output variables and using those inputs whose correlation coefficients have large absolute values [31]. In [31], inputs selection for data with only discrete values for which symbols are substituted is done by subordination of attributes.

The data obtained by measurements of SPICE simulation is often differentiated as in [32], delay lines are used as in [7]), or processed by wavelets as in [33]). In [33], authors preprocess the inputs with Haar wavelets. Wavelets transforms have the capability for time-frequency representation of continuous-time (analog) signals and so are related to harmonic analysis. One of the drawbacks of wavelets for the use in black-box modelling of electronic circuits is the fact that they operate on certain time window. Also, when new sample is added to that window, the wavelet transformation may require the information from the ”future” that must be then extracted by extrapolation or fitting. The best data processing method depends on the type of the circuit being modelled, but a good starting point is generating delays because due to their numerical stability and the ease of implementation in circuit simulator.

Regarding the selection of inputs and their processed version, preferably only a limited number of the one or more processed versions of the input is selected. The selection may be manual (i.e. one or more delayed versions of the input may be selected by the user) or automated. In the case of the automated selection, the feature selection method (e.g., a relief algorithm [34]) can be used to select the one or more processed versions of the input that contribute most to the predetermined model accuracy criterion.

It is preferable to scale the data before applying function approximation methods such as ANNs and SVMs. The data is usually scaled linearly into a [-1, 1] range, e.g. as in [7], [32]. Other scaling methods, e.g., the scaled data may be mapped to have a mean value equal to zero and a standard deviation equal to one or log scaling and two-sided log scaling can be used.

C. Stability and robustness

Modern circuit simulators are numerical systems that can have problems with accuracy and stability when simulating electronic circuits and components [1]. Black-box models can further contribute to the numerical instabilities and therefore, it is necessary to determine whether a particular black-box model is suitable for integration into a circuit simulator.

Most designs simulated in SPICE simulators contain discrete active components (mostly modelled by BSIM3v3 models) and passive components and therefore, SPICE simulators are optimised for simulation of such components. Probably due to that reason, some researchers have reported instabilities when implementing behavioural models in SPICE environments (e.g. [17], [32], [35] when dealing with high-order derivatives that are necessary in order to capture memory effects (if derivative approach is used)).

Another factor that influences stability of models are feedback loops in the model, e.g. in any type of recurrent neural networks. The stability analysis of recurrent neural networks is mostly based on simplification of the problem, e.g. by using Lyapunov’s indirect and direct methods in [32], and does not include the numerical stability problems of the circuit simulator. A simulation based approach using Monte-Carlo methods is proposed for the stability tests. In this way, not only stability of the models could be tested, but also their stability within the circuit simulator by simulating the model in a modern circuit simulator during each iteration of the algorithm. In this way, both the instabilities of the model and circuit simulator will be taken into account.

Another important factor is stability of the model under various loads. Cao and Zhang in [36] propose multiple harmonic excitations of the circuit output port in an elaborate way to achieve good coverage of the internal input-neuron space. The model trained using such data will have better generalization properties when connected to unseen loads. This approach is not optimised for the measurement based modelling and relies on accurate nonlinear frequency domain simulations (and then applying inverse fourier transform) to obtain the load training data and therefore, it is out of the scope of this work.

Using dual-stage architecture of an electronic circuit black-box model can increase stability of the model in modern circuit simulators, improve robustness of the model in situations that are not used for learning, increase accuracy and improve connection of the models to the modern circuit simulators. The first stage consists of the functional approximation method, and the second stage is built to improve connection to the circuit simulator, and to reduce the complexity of the modelling problem for the functional approximation method as described in [7], [8]. Another type of dual-stage architecture is the use of simple equivalent circuit models with universal approximation methods e.g. as done in [37] where existing knowledge in the form of simple equivalent circuits is used with ANNs and demonstrated for modelling of MESFETs. The usage of second stage (e.g. by simple equivalent circuits) simplifies the generalisation problem of the function approximation method.

IV. CONCLUSION

The black-box modelling of electronic circuits will remain interesting area of research for both industry and academia due to many favourable properties (such as fast model building and execution) of black-box modelling when compared to classic physical based modeling. In this paper, a brief overview of the state-of-the-art in black-box modelling of electronic circuits is

given together with pointers were future research could go. Support vector machines seem to the a promising function approximation method suitable for black-box modelling of electronic circuits. Feature selection algorithms can be used to automatically select adequate inputs. The usage of two-stage models can improve stability, robustness and accuracy of the model when implemented in modern circuit simulators. The model stability tests should also include the effect of numerical instabilities of the circuit simulator.

andro.broznic@fer.hr

Abstract-In this paper a 2.5-GHz GaN power amplifier is presented. The amplifier is designed to achieve unconditional stability in the frequency range from DC to 6 GHz. The circuit-EM co-simulation model of the complete amplifier, including transistor model, passive components, connector model and the EM model of the critical parts of the design is created. The impact of each component is addressed. The amplifier is processed and measured, the measurements are compared to simulations and a good agreement is achieved. The amplifier parameters power added efficiency (PAE), drain efficiency (DE) and IP3 are measured and compared to results published in open literature.

I. INTRODUCTION

The growing market of wireless communications operating at GHz frequencies continues to push boundaries of transistor development. Significant effort is invested in high performance microwave transistors based on Gallium Nitride. GaN-based high electron mobility transistors (HEMTs) have many advantages over other existing technologies, such as high output power density, high operating voltage, higher impedance, higher operating temperatures [1] and better noise performance (compared to MESFET's) [1, 2] which makes it ideal for RF power amplifier applications.

RF power amplifiers are mostly processed using MMIC technology [3-5] or a printed circuit board technology [6, 7]. If a printed circuit board technology is used, external SMD passive components are typically employed for impedance matching and bias supply network. However, SMD passive components are not ideal; at RF frequencies their characteristics are significantly different from the nominal characteristics [8]. Models of passive components that capture their behavior at high frequencies are therefore needed to achieve better agreement between measurements and simulations. This in return enables optimization of a design in an early stage of design cycle, therefore reducing the time and expenses necessary for the project.

A power amplifier using the same transistor as in this paper is designed in [5]. 3D simulations and model developing for lumped elements, bond wires and coaxial connectors have been considered for the power amplifier design in [6]; however, no additional information on the modeled structures or the impact of the modeled components on the modeled amplifier characteristics has been given. The main focus of this paper is the characterization and optimization of the RF power amplifier realized in a printed circuit board technology with respect to the high frequency models of passive components. Simple circuit models for each of the modeled components are given and the impact of each modeled component on the amplifier characteristics is addressed.

The design process and simulation models are presented in Section II. The simulations are compared to measurements in Section III. Section IV concludes the paper.

II. POWER AMPLIFIER DESIGN AND SIMULATION MODEL

The schematic of the amplifier is based on [9] and is shown in Fig. 1. The substrate on which the amplifier is designed is 1.55-mm thick FR4 (ε_r = 4.4, $tan\delta$ = 0.02 at 1 GHz). The transmission line technology used for interconnects is a grounded coplanar waveguide. The transistor model used in simulations is the small-signal S-parameters model provided by the manufacturer [9]. The values of the passive components and transmission line lengths are optimized to achieve impedance matching and maximum gain at 2.5 GHz. The parameters of the optimized passive components and transmission lines are shown in Fig. 1. The high frequency models of passive components, connector model and T-junction EM-based model used in the simulations are discussed in the rest of this section. Four amplifier models are created and compared to measurements to assess the effect of each of the components described in this section:

a) 1st model – includes only the transistor model, transmission line models and ideal passive component models.
b) 2nd model – the same as the 1st model, but with the high frequency passive component models instead of the ideal ones.
c) 3rd model – the same as the 2nd model, but with the connector model added.
d) 4th model – the same as the 3rd model, but with the additional EM-based models of T-junctions.

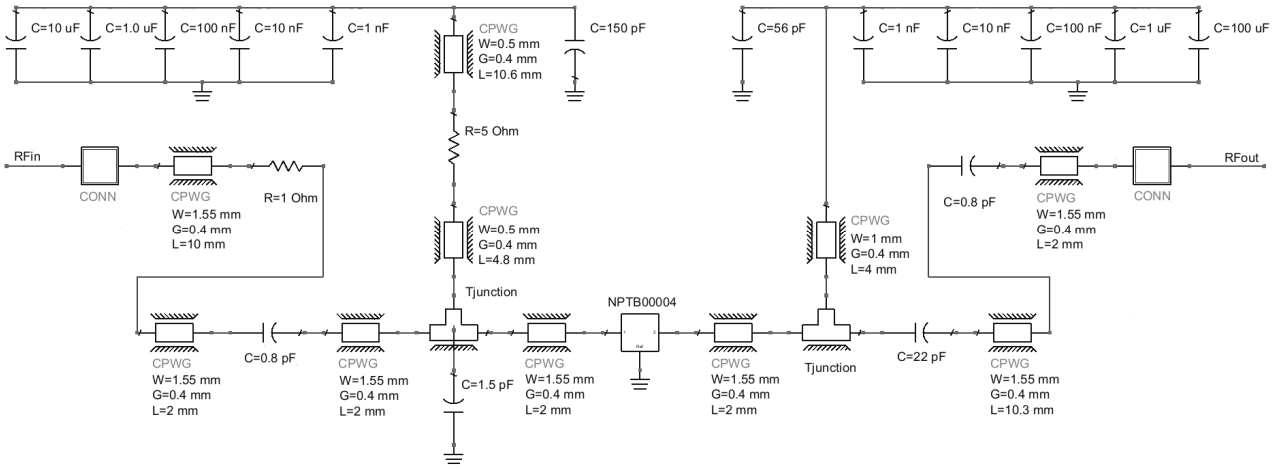

Figure 1. The schematic of the designed RF power amplifier.

High frequency passive components models

High frequency capacitor and resistor models and their corresponding parameter values of 0805-package on grounded coplanar waveguide and 1.55-mm thick FR4 substrate [10] used in simulations are shown in Fig. 2 and Fig. 3, respectively.

Connector model

The connectors at RF ports used in simulations are Southwest Microwave's 292-04A-5 end-launch connectors and are mounted without soldering [11]. The connector model [12] used in the simulations is shown in Fig. 4. Three coplanar waveguide lines of different lengths (30 mm, 80 mm and 130 mm) are used to optimize the model.

Circuit-EM co-simulation

The segmentation technique is used to characterize the grounded coplanar waveguide T-junctions present in the design: electromagnetic simulation of the T-junction is performed and an optimization of the T-junction grounded coplanar waveguide model [13] is carried out to extract the parameters of the model. The model and the corresponding parameters used in the simulation are shown in Fig. 5.

Achieving unconditional stability

Finally, having the complete model, the stability of the amplifier is assessed. One of the most challenging problems in the design of RF amplifiers is its stability at low out-of-band frequencies [14]. In particular, simulations of this amplifier showed possible instability around 1 GHz. One of the possible solutions is adding a series gate resistance [14, 15]. The simulations showed improvement even with small values of the resistance. The final design is unconditionally stable with the 1-Ω series gate resistance. The associated simulated gain loss is only 0.1 dB.

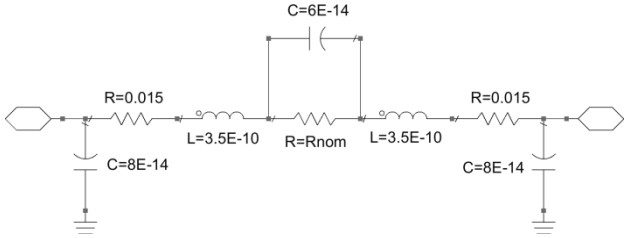

Figure 3. High frequency 0805-package resistor model on grounded coplanar waveguide and 1.55-mm thick FR4 substrate [10].

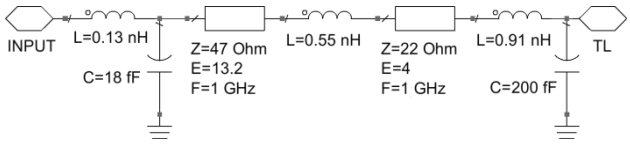

Figure 4. End-launch connector model [12] with optimized parameters for Southwest Microwave's 292-04A-5 connector.

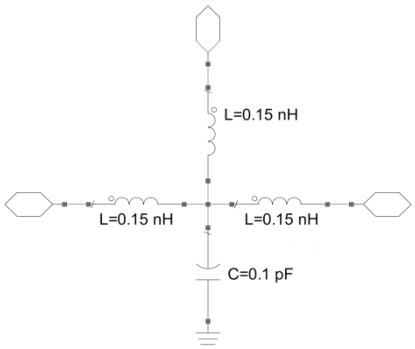

Figure 5. Grounded coplanar waveguide T-junction model [13] with optimized parameters.

III. MEASUREMENTS

S-parameters

The amplifier bias point for the measurements is V_{DS} = 14 V and I_{DS} = 50 mA. The comparison of four models and the measurements is shown in Fig. 6. The 1st model does not predict the amplifier characteristics at satisfactory level (Fig. 6a). Adding high frequency passive components models improves the amplitude characteristics up to 4 GHz (Fig. 6b). Adding connector model improves the phase characteristic up to 4 GHz (Fig. 6c). Finally, the frequency of the maximum gain is matched to the measured one in the 4th model by adding the EM-based T-junction model (Fig. 6d). It should be noted that the frequency of the maximum gain is shifted from 2.5 GHz to 2.35 GHz. The measured gain at 2.35 GHz is 14.1 dB, while the simulated one is 16.7 dB. The reason for this difference is most probably the tolerance of the nominal values of passive components in the RF nets.

The comparison between the measurements and the 4th model show good agreement, similar to the comparison between the measurements and simulations presented in [6] (it should be noted that the amplifier modeled in [6] is a broadband amplifier, while the amplifier presented here is a narrowband amplifier which is expected to be easier to model). However, the agreement is not perfect. One of the reasons for that are the parameters of the passive component models whose values are taken based on the package dimensions as published in [10], although they depend not only on the package dimensions but also on the process technology and mounting scheme. Another reason is the tolerance of the nominal value of components (both passive and active). This is especially significant for the transistor and the components in the RF input and output lines. At higher frequencies the characteristics of the FR4 substrate, which is not meant to be used at RF, start to play a role as well.

K-factor

Rollet's stability factor (K-factor) is often used to determine the stability of an amplifier. It is calculated using (1) [14].

$$K = \frac{1 - |S_{11}|^2 - |S_{22}|^2 + |\Delta|^2}{2|S_{12}S_{21}|} \tag{1}$$

where

$$\Delta = S_{11}S_{22} - S_{12}S_{21}. \tag{2}$$

The simulated and measured stability factors are shown in Fig. 7. The processed amplifier is unconditionally stable from DC to 6 GHz, as was predicted in simulations. It is interesting to note that the measured Rollet's stability factor indicates better stability than the simulated Rollet's stability factor.

PAE, DE, IP3

The drain efficiency (*DE*) and power-added efficiency (*PAE*) are given by (3) and (4), respectively [14].

$$DE = \frac{P_{RFout}}{P_{DC}} = \frac{P_{RFout}}{V_{DC}I_{DC}} \tag{3}$$

$$PAE = \frac{P_{RFout} - P_{RFin}}{P_{DC}} = \frac{P_{RFout} - P_{RFin}}{V_{DC}I_{DC}} \tag{4}$$

The measured gain, output power, *DE* and *PAE* as a function of the input power are shown in Fig. 8.

The input third-order intercept point (*IIP3*) is a linearity measure used for weakly nonlinear systems and devices. The definition used in this paper is based on the intermodulation products [14]. The amplifier is fed with two sine tones with a 100 kHz frequency difference. The *n*-th order intermodulation products appear at *n* times the frequency spacing of the input tones. The *IIP3* extrapolation is shown in Fig. 9.

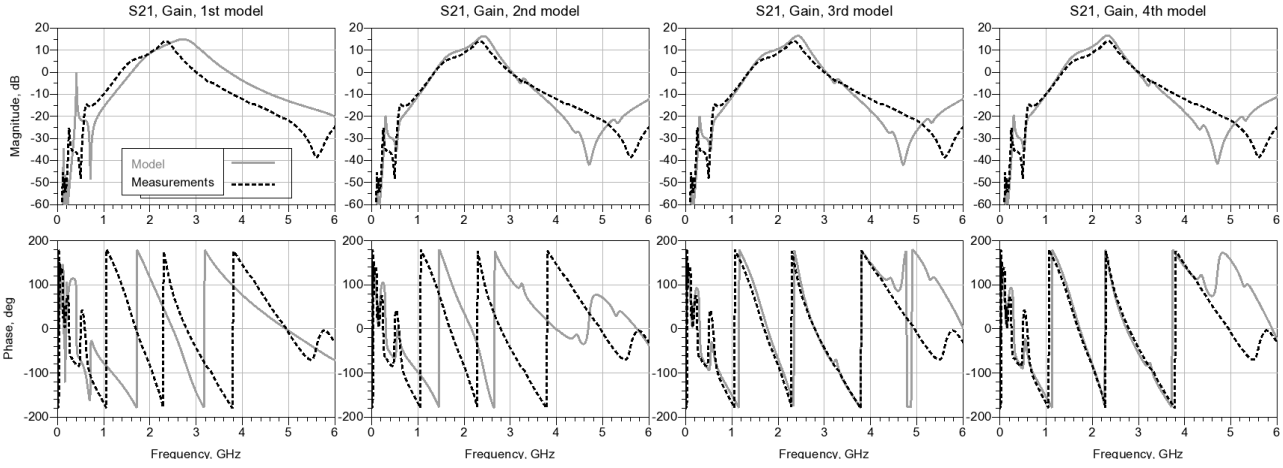

Figure 6. Comparison between the measurements and four models: a) 1st model, b) 2nd model, c) 3rd model and d) 4th model.

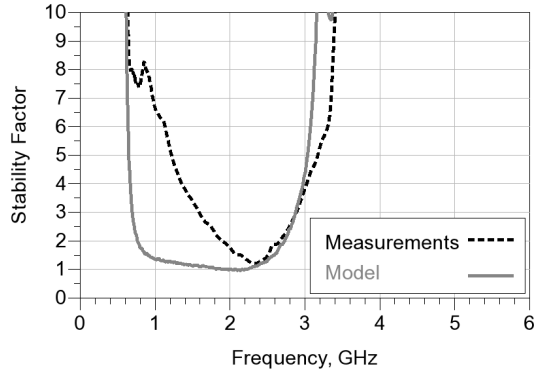

Figure 7. The measured and simulated stability factor for the amplifier.

[4]	3	18	21	20	105	-	-
[5]	5.7	8	-	28	60	30	40
[6]	0.35 - 8	9	40	28	650	20	-
[7]	1e-3 - 3.4	14.6	33.9	28	450	23.5	-

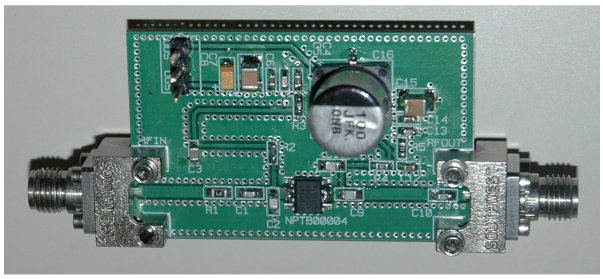

Figure 10. The processed amplifier printed circuit board.

Note that only the small-signal model of the transistor is available for NPTB00004, and therefore *PAE*, *DE* and *IIP3* are not simulated.

The measured amplifier performance is compared to the performance presented in several other papers and is shown in Table 1.

The processed amplifier printed circuit board is shown in Fig. 10.

IV. CONCLUSION

An unconditionally stable impedance matched 2.5-GHz GaN HEMT amplifier is designed in printed circuit board technology, simulated, optimized and measured. The passive components, the connectors and the T-junctions are recognized as parts of the design that need to be carefully modeled to predict the amplifier characteristics correctly and therefore to optimize the design. The final model shows a good agreement between the simulated and measured characteristics. A clear improvement in modeling results is seen when the high frequency passive components models, the connector model and the EM-based T-junction model are included in the simulation model as opposed to the simulation model with the ideal, low-frequency models.

The measured amplifier gain at 2.5 GHz is 11.8 dB for the power consumption of 50 mA at 14 V power supply. The measured *IIP3* is 20.7 dBm. The output power at 1-dB compression point *P1dB* is 24.8 dBm with the associated *PAE* of 40.8% and *DE* of 44%.

ACKNOWLEDGMENT

The authors would like to thank Renaud Gillon from the On Semiconductor for many helpful discussions, and Silvio Hrabar from the University of Zagreb for his support with the measurements.

Pseudo-Exponential Computational Circuit with Improved Accuracy and Frequency Response

Cosmin Popa

Faculty of Electronics and Telecommunications
University Politehnica of Bucharest
Bucuresti, Romania

Abstract – A new higher-order CMOS current-mode pseudo-exponential circuit will be presented. The advantage of the circuit with respect to the previous reported similar ones is the smaller value of the limited expansion error obtained by using a higher order approximation of the exponential function. The circuit presents the important advantage of the independence of the output current on technological parameters. Due to the strong inversion operation of all MOS transistors and to the current-mode operation of the circuit, the circuit frequency response can be strongly improved. The second-order effects will be taken into account for evaluating the total error of the circuit core, resulting an additional error summed to the error caused by the neglecting of the superior-order terms from the exponential function Taylor series expansion. The circuit area is relatively small due to the exclusively utilization of MOS transistors.

1. INTRODUCTION

The exponential circuits represent important building blocks for telecommunication applications, medical equipment, hearing aid, disk drives and, especially, for analog signal processing.

The exponential function could be easily obtained in the bipolar technology from the exponential characteristic [1] of the bipolar transistor. The nonzero value of the base current, especially for pnp transistors and the temperature dependence of the bipolar transistor parameters (the thermal voltage is linear increasing with temperature and the saturation current has an exponential dependence on temperature) introduces relatively large errors in the exponential characteristic.

In CMOS technology, the exponential law is available only for the weak inversion operation of the MOS transistor. The great disadvantage of the computational circuits using MOS transistors in weak inversion is the poor circuit frequency response caused by the much smaller drain currents available for charge and discharge the parasite capacitances of the MOS transistors. Thus, circuits realized in CMOS technology that require a good frequency response can be designed using only MOS transistors working in strong inversion (usually in saturation). In order to obtain the exponential function using the square characteristic of the MOS transistor in saturation, the original idea is to approximate the exponential function with its $n-th$ order expansion (the polynomial series). The approximation error is proportional to the number of terms neglected in the expansion.

In this paper, an original CMOS VLSI current-mode pseudo-exponential circuit will be presented based on an excellent approximation of the exponential function by its higher-order limited Taylor series expansion. The computed exponential function has the important advantage given by the independence of the output current on technological parameters. Additionally, the circuit accuracy could be strongly increased by considering superior-order terms from the exponential function expansion.

2. THEORETICAL ANALYSIS

For applications that require a better accuracy that could be obtained using the second-order approximations of the exponential function described in [2]-[7], the circuit proposed in this paper uses a higher-order approximation, expressed as:

$$\exp(x) \cong 1 + x + \frac{x^2}{2} + \frac{x^3}{6} + \ldots \quad (1)$$

for $x << 1$. Using the ratio of currents I_{IN} and I_O as expansion variable, expression (1) could be re-written as:

$$I_O \exp\left(\frac{I_{IN}}{I_O}\right) \cong I_O\left[1 + \frac{I_{IN}}{I_O} + \frac{1}{2}\left(\frac{I_{IN}}{I_O}\right)^2 + \frac{1}{6}\left(\frac{I_{IN}}{I_O}\right)^3\right] + \ldots \quad (2)$$

I_{IN} is the input current, while I_O represents the reference current.

2.1 The implementation of the squaring function

The core of the system is represented by the squaring circuit based exclusively on MOS transistors working in saturation for improving the circuit frequency response ($x = I_{IN} / I_O$).

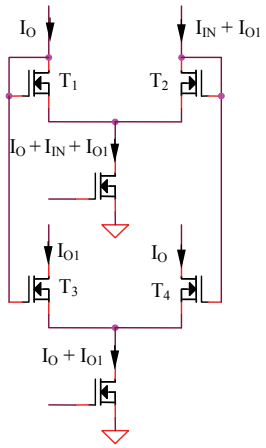

Figure 1 - The CMOS squaring circuit

Because:

$$V_{GS_1} + V_{GS_4} = V_{GS_2} + V_{GS_3}, \tag{3}$$

it results:

$$2\sqrt{I_O} = \sqrt{I_{O_1}} + \sqrt{I_{IN} + I_{O_1}}, \tag{4}$$

equivalent to the following dependence of I_{O_1} current on the input current I_{IN} and on the reference current I_O:

$$I_{O_1} = I_O - \frac{I_{IN}}{2} + \frac{I_{IN}^2}{16 I_O}. \tag{5}$$

The entire implementation in CMOS technology of the previous current squaring circuit is presented in Fig. 2.
Designing a linear relation between the currents from the previous circuit:

$$I_{OUT} = 16 I_{O_1} - 16 I_O + 8 I_{IN}, \tag{6}$$

it results that the output current will be proportional to the square of the input current:

$$I_{OUT} = \frac{I_{IN}^2}{I_O}. \tag{7}$$

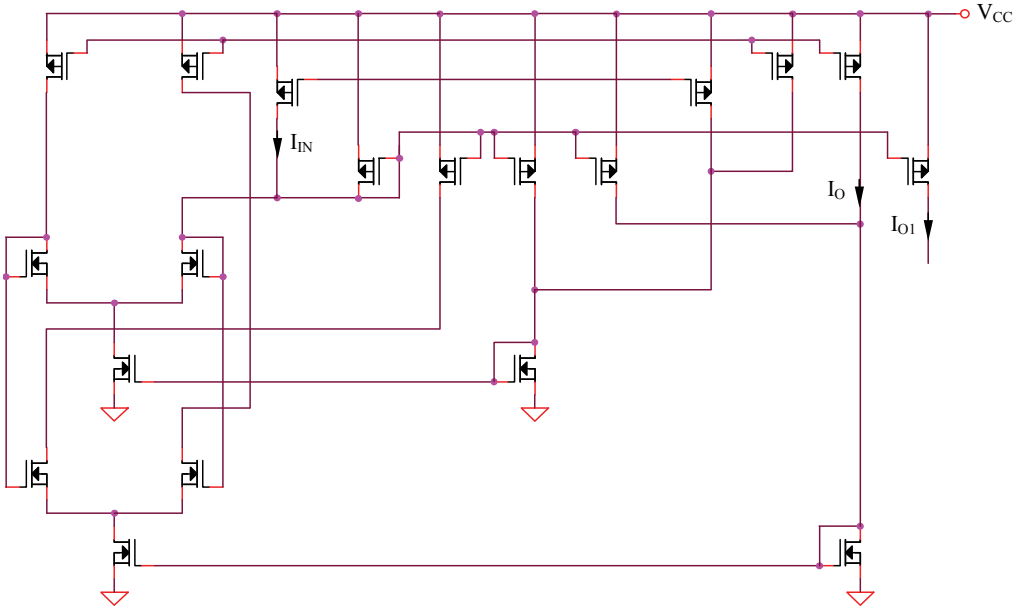

Figure 2 - The CMOS current squaring circuit

The symbolic representation of the current squarer from Fig. 1 is presented in Fig. 2.

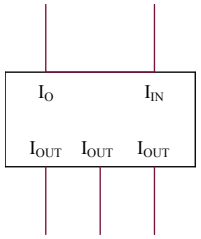

Figure 3 - The symbolic representation of the current squarer from Fig. 2

2.2 The pseudo-exponential function generator

The block diagram of the exponential function generator circuit is presented in Fig. 4, consisting in n identical current squarers from Fig. 3 for a $n-th$ order polynomial series expansion of $\exp(x)$ function and in a block that computes a_k coefficients for $k = 0,1,...,n+1$. The advantage of this implementation is that a very good precision of the circuit could be achieved by increasing the value of n.

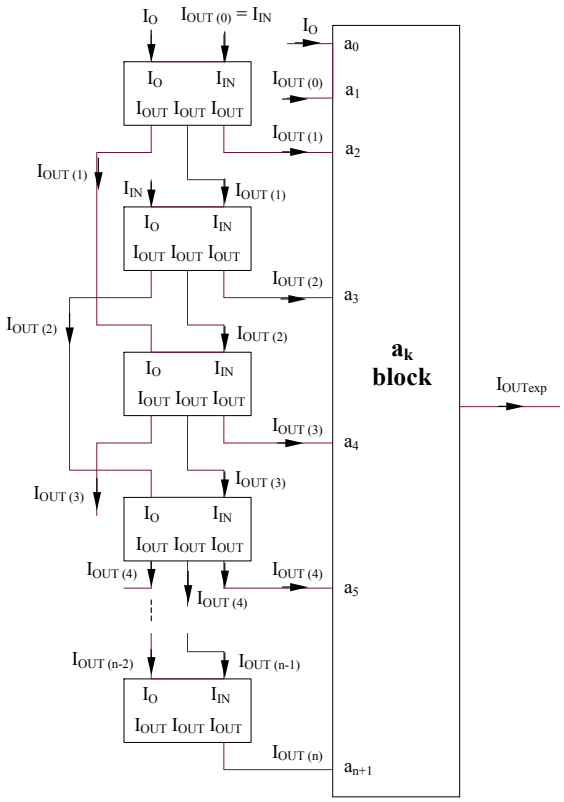

Figure 4 - The block diagram of the exponential function generator circuit

The implemented currents using the previous circuits are:

$$I_{OUT(1)} = \frac{I_{IN}^2}{I_O}, \tag{8}$$

$$I_{OUT(2)} = \frac{I_{OUT(1)}^2}{I_{IN}} = \frac{I_{IN}^3}{I_O^2}, \tag{9}$$

$$I_{OUT(3)} = \frac{I_{OUT(2)}^2}{I_{OUT(1)}} = \frac{I_{IN}^4}{I_O^3}, \tag{10}$$

…

$$I_{OUT(n)} = \frac{I_{OUT(n-1)}^2}{I_{OUT(n-2)}} = \frac{I_{IN}^{n+1}}{I_O^n}. \tag{11}$$

The "a_k" block is implemented using simple and multiple current mirrors and must be able to compute the a_k ponders from (1). The output current of this block, $I_{OUT\exp}$ will be proportional to the higher-order approximated exponential function. In order to increase the circuit accuracy, the number of squaring blocks from Fig. 4 could be increased. So, a compromise between the circuit complexity and its precision must be made. The circuit accuracy is also increased by the independence of the output current on technological parameters.

The current-mode operation of the circuit, associated to the biasing in saturation of the MOS devices produce an important increasing of the circuit frequency response.

The removing of any resistors from the circuits allow an relatively large decreasing of the silicon area consumption and an important increasing of the circuit precision. The CMOS squaring circuit could be replaced by any other squaring circuit realized in CMOS technology, with the only limitation of using exclusively MOS transistors working in saturation for obtaining a good frequency response.

2.3 Analysis of errors introduced by the second-order effects

All of the circuits presented above are affected by the second-order effects that degrade the quadratic law of the MOS transistor. These undesired effects are modeled by the following relations (channel-length modulation (12) and mobility degradation (13)).

$$I_D = \frac{K}{2}(V_{GS} - V_T)^2(1 + \lambda V_{DS}) \tag{12}$$

$$K = \frac{K_0}{[1 + \theta_G(V_{GS} - V_T)](1 + \theta_D V_{DS})} \tag{13}$$

Considering that the design condition $\lambda = \theta_D$ is fulfilled, the gate-source voltage of a MOS transistor working in saturation at a drain current I_D will be:

$$V_{GS} = V_T + \sqrt{\frac{2I_D}{K}} + \theta_G \frac{I_D}{K}. \quad (14)$$

Taking into account the second-order effects, the expression (7) of the output current for the circuit from Fig. 2 will be affected by a small error:

$$I_{OUT} = \frac{I_{IN}^2}{I_O} + \varepsilon. \quad (15)$$

3. SIMULATION RESULTS

The $(I_{OUT}/16)(I_{IN})$ simulation for the squaring circuit from Figure 2 is presented in Figure 5. I_O current is equal with *1mA* and I_{IN} current varies between *0* and *3mA*.

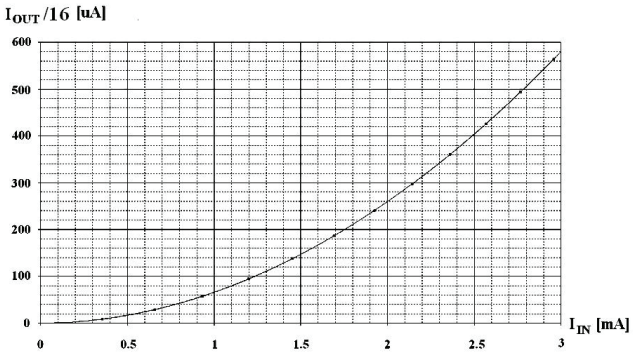

Figure 5 - The $(I_{OUT}/16)(I_{IN})$ simulation for the squaring circuit

4. CONCLUSIONS

A new higher-order CMOS current-mode pseudo-exponential circuit has been presented. The advantage of the circuit with respect to the previous reported similar ones [6], [7] is the smaller value of the limited expansion error obtained by using a higher order approximation of the exponential function. The circuit presents the important advantage of the independence of the output current on technological parameters. Due to the strong inversion operation of all MOS transistors and to the current-mode operation of the circuit, the circuit frequency response was strongly improved. The second-order effects will be taken into account for evaluating the total error of the circuit core, resulting an additional error summed to the error caused by the neglecting of the superior-order terms from the exponential function Taylor series expansion. The circuit area is relatively small due to the exclusively utilization of MOS transistors.

Abstract - The negative capacitance circuits are very interesting analog building blocks with many possible applications like the compensation of undesired parasitic capacitance, bandwidth enhancement of amplifiers, equalization filters design without passive inductors, etc. This paper presents a method for improving and controlling CMOS floating negative capacitance frequency response. Since the negative capacitance is generated by the simple and known negative impedance converter (NIC), the proposed method is applicable for negative inductance and resistance also.

The proposed method is simulated and verified using standard 0.35µm and 0.18µm CMOS processes.

I. INTRODUCTION

The negative capacitance circuits or negative capacitance generators (NCG) are very useful analogue building blocks, used for numerous different applications enabling:

- The improvement of existing structures, through the compensation of undesired parasitic capacitance, like bandwidth enhancement of various kind of amplifiers [6], [7], speed enhancement of some DAC architectures, improvement of ESD protection circuits [3], improvement of active inductor design [1], [4], etc.
- The design of new circuit architectures like the new compact equalization filters, new RC and LC oscillator structures etc.

There are many different possibilities for grounded or floating negative capacitance generation, mostly known for decays.

Generally, any well known negative impedance converter (NIC), which employs operational amplifiers or current conveyors, can be used. Negative capacitance generated using such an approach is accurate, with a large allowed signal swing. The disadvantages are that such an approach requires a large area and increased power, especially for floating capacitor generation, and mostly performs with poor higher frequency limit.

There are also several known simple structures which can be used as a floating NCG, like a common source amplifier with cross-coupled capacitors and source's parallel R-C pairs [2]; or a very effective NCG known as the relaxation generator, with cross-coupled MOSFETs, described in [3].

Although the last structure generates a negative resistance as well as a negative capacitance and performs with an inevitable noise figure and some linearity degradation, it is quite simple, offers great possibilities for improvements and control and was therefore chosen for the presented analysis and design.

II. IMPLEMENTATION

A. A Generalized Negative Capacitance

As it is mentioned previously, a simple way to generate a floating negative capacitor is by using a cross-coupled pair of transistors in order to create a positive feedback.

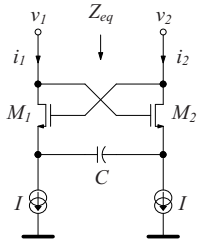

Figure 1. The simple negative capacitance generator

The positive feedback loop formed by transistors M_1 and M_2 makes a difference in the output currents to have an opposite polarity to the differential voltage. Thus, the equivalent output impedance has a negative value.

From the small signal analysis of the proposed circuit, after disregarding the channel length modulation, the equivalent impedance is given by

$$Z_{equ} = -\frac{1}{sC}\frac{g_m + s(C_{GS} + 2C)}{g_m - sC_{GS}} \qquad (1)$$

As long as $f << f_T$, where f_T is the unity gain frequency or transition frequency of the used MOSFETs, the equivalent impedance can be approximated by

$$Z_{equ} \approx -\frac{1}{sC} - \frac{(C_{GS} + 2C)}{g_m C}, \qquad f << f_T \qquad (2)$$

Equivalent impedance at the output is the complex impedance with reactive and resistive parts, and it is easy to notice that a similar circuit, with a shorted capacitor *C*, can be used for negative resistance generation. Further modification proposed in [5] enables a negative inductance generation as well.

Figures 2 (a) and (b) show the schematic diagrams of a similar negative resistance circuit and a negative inductance circuit [5], respectively.

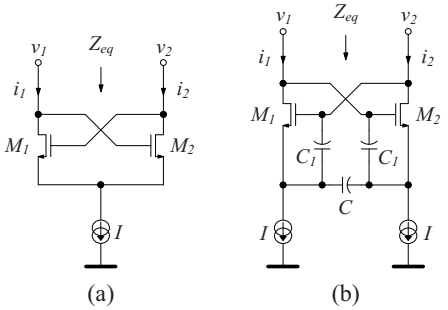

Figure 2. Schematic diagrams of (a) negative resistance and (b) negative inductance generators

B. A Simplified Implementation Model

The previously described NCG is loaded with the rest of the circuits where it acts as a negative capacitor, and all characteristics, including the possible stability issues, hardly depend on the implementation details. For further analysis, such an undefined load will be replaced by a dynamic one, with MOSFETs shown as current sources, for simplicity. A corresponding schematic diagram is shown by Figure 3.

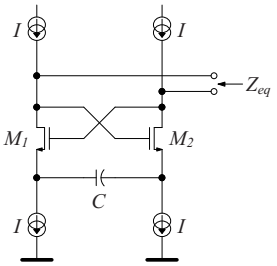

Figure 3. The simple NCG with load

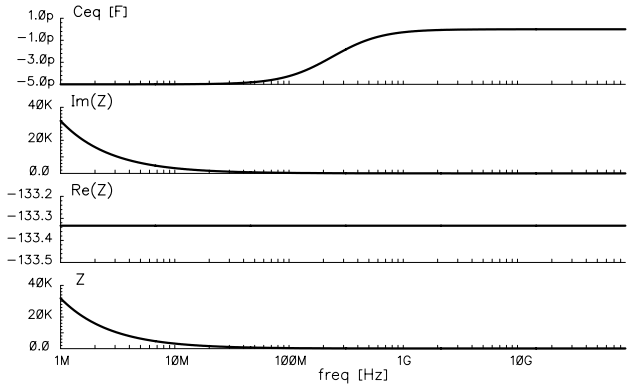

Figure 4. Negative capacitance and complex impedance, the simple NCG model

Assuming that MOSFETs are ideal, without any parasitic capacitance and with a realistic but constant transconductance g_m, an equivalent negative capacitance with an equivalent complex impedance are shown in Figure 4. As expected, the capacitance value *C* defines the value of the equivalent negative capacitance, while the transconductance value defines the negative resistance value.

The capacitor *C* and the MOSFET's transconductance define the higher frequency limit for the used NCG as well.

Figure 5 shows the equivalent negative capacitances for different capacitor *C* values. In the ideal case, only the sign would differ.

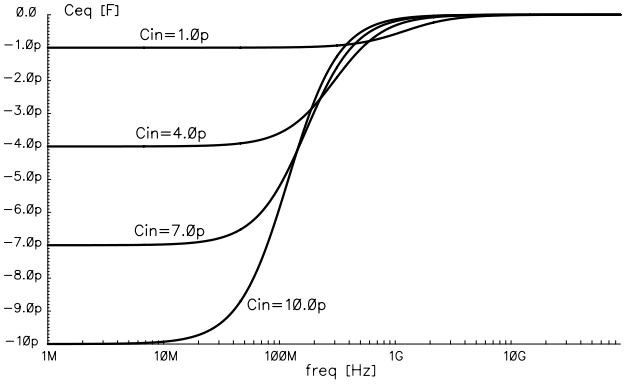

Figure 5. Negative capacitance versus input capacitance value, model

The capacitance *C* also defines the frequency range. To increase the frequency range of the proposed NCG it is necessary to decrease the capacitance *C* value. Usually this is not acceptable in the real design.

There is another way to enlarge the frequency range. The currents and the dependent transconductance should be increased. For the assumed ideal MOSFETs, replaced by dependent sources with constant transconductance, the current *I* value changes do not produce any effect. Nevertheless, the transconductance changes perform as expected, as shown by Figure 6.

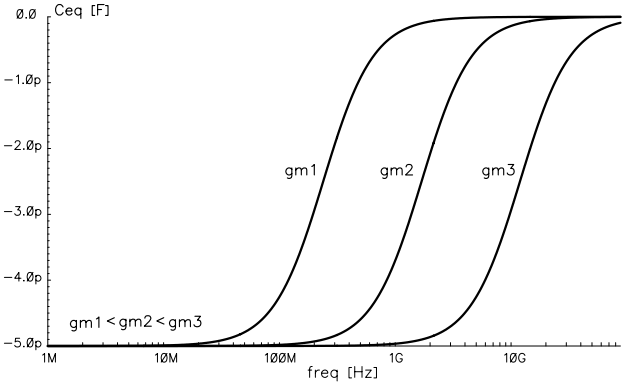

Figure 6. Negative capacitance versus transconductance, model

The high frequency limit of the proposed NCG depends on the current *I* value and depending MOSFETs transconductance. This enables an easy control of the high

frequency limit which allows an easy calibration and frequency control for some RC oscillator classes.

The equivalent complex impedance, with all its parts, is shown in Figure 7.

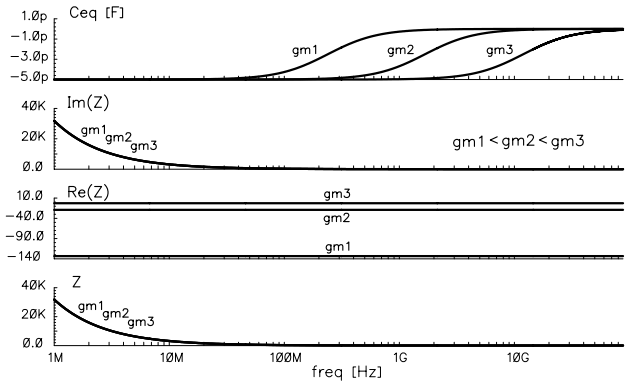

Figure 7. Negative capacitance and complex impedance versus transconductance, model

III. VERIFICATION

A. General Information

The circuits were designed, simulated and verified using NCSU CDK, which is a collection of MOSIS fabrication processes available for public download, and ngspice v22 simulator. The technologies used were tsmc_02, tsmc_03 and tsmc_04_4m. Simulations were made across all process corners and the temperature range for all cases.

The proposed design can be processed in any available mixed–signal technology with simple re-calculations and optimizations due to the specific characteristics of the technology.

B. Physical Implementation

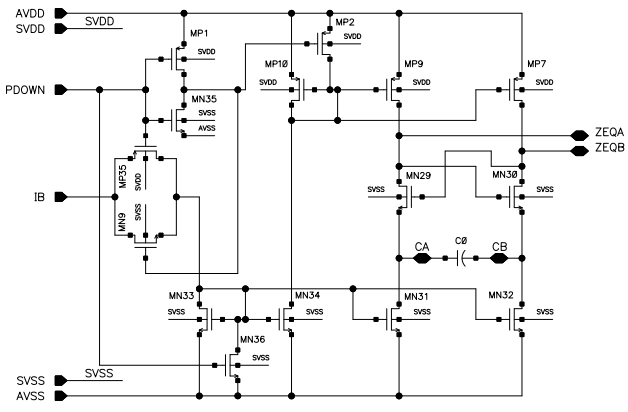

Figure 8. Negative capacitance generator

Figure 8 shows the real implementation of the proposed NCG with ideal current sources replaced by current source and sink mirrors. The implemented power-down circuitry enables a parallel connection between multiple NCGs. Such parallel connection is actually a transistors W/L ratios multiplication and is equivalent to the previously described transconductances multiplication. To enable fine control, the proposed NCG is biased by *IB* current.

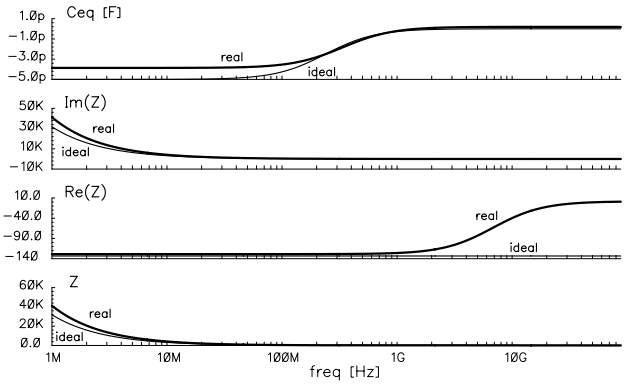

Figure 9. Negative capacitance and complex impedance, model and real circuit, comparison

Figure 9 shows the comparison between model's and the realistic NCG's behaviors. The main difference is caused by the real transistors parasitics, especially by the C_{GS}. It is inevitable but can be compensated by an increased capacitance *C* value.

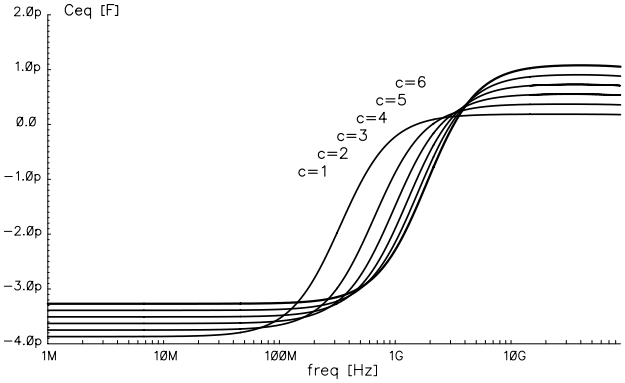

Figure 10. Negative capacitance versus transconductance

Figure 10 shows the high frequency limit characteristics for a different number of parallel NCGs shown by Figure 8. One should notice that a parallel combination of simple NCGs significantly increases the frequency range for almost a decade.

Unlike the previously used NCG model, the real circuit allows a high frequency limit control by current.

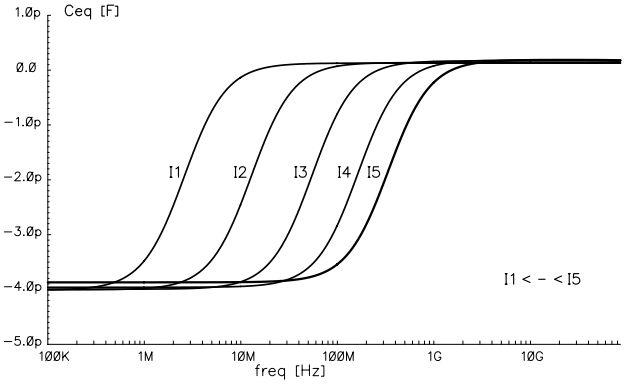

Figure 11. Negative capacitance versus current

Figure 11 shows the high frequency limit characteristics for different currents, controlled by the *IB*.

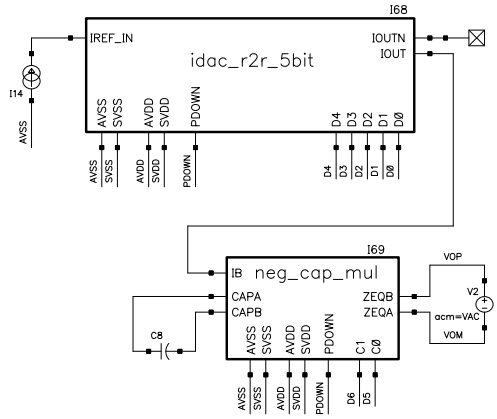

Figure 12. Controled NCG, block diagram

Figure 12 shows the final negative capacitance circuit, with high frequency limit controllable by a bias current and transconductances. Control with the bias current is fine and accurate, with a simple IDAC; the transconductance control is coarse, with a controlled number of connected simple NCGs.

Figure 13 shows the frequency characteristic of the proposed NCG, generated with 3 coarse ranges. In order to keep the picture clear only 3 fine values per range are shown.

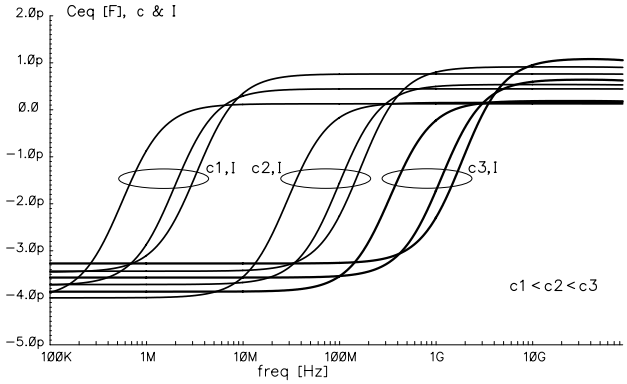

Figure 13. Negative capacitance versus transcoductance and current

IV. CONLUSION

A simple method for increasing and controlling the high frequency limit for the simple NCG is presented. The significantly increased frequency range and the accurate high frequency limit control allow an efficient design of some RC oscillator classes.

The same method can be used for the value and the frequency limit control of the negative resistance and the frequency range of the negative inductance shown in Figure 2.

josip.zilak@fer.hr

Abstract - Impact of integrated bipolar transistor parameters on the double-balanced Gilbert mixer performance is analyzed. The used Gummel-Poon transistor model is based on Horizontal Current Bipolar Transistor (HCBT) integrated technology. Intermodulation distortion and conversion gain are analyzed by harmonic balance simulations. Due to the flexibility of HCBT technology, transistor parameters can be adjusted and their impact on circuit characteristics is examined. Analysis starts at lower level, where distortion of differential amplifier is studied and then it is expanded to the whole mixer where the influence of the each circuit part on distortion is examined. The achieved values of input third-order intercept point (IIP3) of 18 dBm and conversion gain of -3.3 dB for mixer with default transistor parameters are comparable with the commercial mixers. Parameter optimization gives a 4-5 dBm increase of IIP3 with small conversion gain decrease of -0.5 dB. The linearity increase depends on the mixer operating frequency.

I. INTRODUCTION

Mixers are the three port active or passive devices. They are designed to provide both, a sum and a difference frequency at a single output port when two distinct input frequencies are inserted into the two input ports. This process is called frequency conversion and is found in most communication transceivers. Most amplitude modulation (AM), single-side band (SSB) and digital transmitters require mixers that provide up conversion where an output signal is at higher frequency then the input signal. Receivers require down conversion mixers that are lowering received frequency allowing more efficient signal processing. Passive mixers are widely used because of their relative simplicity, wide bandwidth and good linearity. The devices of choice for modern mixer designers are Schottky diodes, GaAs FETs and CMOS transistors. Active mixers based on BJT and CMOS differential pairs are used in integrated circuits (IC). They are better for IC implementation but achieving good linearity is more difficult. The single and double balanced mixers providing necessary port to port isolation are used both in passive and active mixer implementation.

In modern analog radio frequency (RF) circuits, intermodulation distortion is one of the most important effects generated because of nonlinear nature of active elements used in such circuits. Spectral efficiency and signal amplitude variation between transmitter and receiver impose high demands on RF circuit linearity, making intermodulation distortion analysis highest priority of circuit designers.

Distortion is analyzed using different techniques in the literature. The Volterra series is the most popular symbolic method for this analysis which combines the theory of convolution and Taylor series expansion. This powerful technique, most commonly used in RF distortion analysis, is very complex and does not offer easy solutions. The resulting distortion expressions often contain numerous terms that offers little intuition and physical insight [1], [2], [3], [4].

In this paper a double-balanced down-conversion mixer realized in Horizontal Current Bipolar Transistor (HCBT) technology [5], [6] is analyzed by circuit simulations. Influence of the transistor parameters on the electrical performance is investigated.

II. DOUBLE-BALANCED MIXER

The double-balanced mixer configuration is widely used in RF integrated circuits. It offers advantages such as sufficient gain, noise figure, very good port isolation and performance less sensitive to the impedance mismatch at its ports. Besides, moderate local oscillator (LO) drive is needed for the operation and mixer is easily integrated with other circuits which makes it preferred mixer implementation for most RF systems. Invented by Gilbert [7], the active mixer is based on current commutation

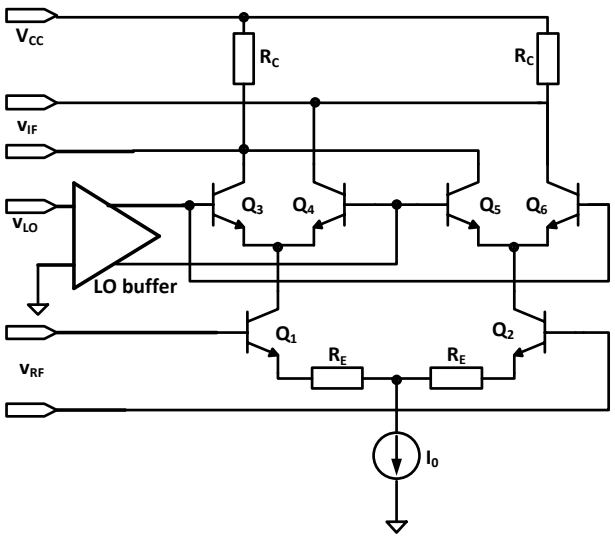

Figure 1. Double-balanced mixer

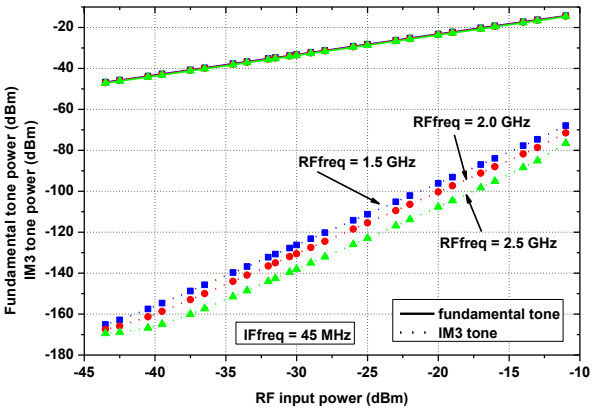

Figure 2. Simulated intermediate frequency (IF) output power of fundamental and IM3 tone versus RF input power for several RF input frequencies and LO input power P(LO)=0 dBm

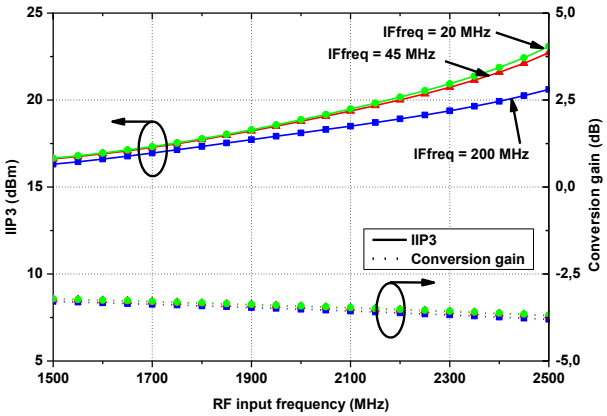

Figure 3. Simulated mixer third-order intercept point (IIP3) and conversion gain versus RF frequency for several output intermediate frequencies (IF), P(RF)= -30 dBm, P(LO)=0 dBm

implemented by bipolar transistors as shown in Fig. 1. Differential pair Q_1, Q_2 at the RF input represent the transconductance stage that transforms the input voltage signal to the current. Mixer linearity and gain performance is usually limited by this stage. Resulting current is then commutated by switching quad (transistors Q_3, Q_4, Q_5 and Q_6) producing frequency conversion. Therefore, the voltage swing applied to the LO port is large enough to switch on and off the switching quad transistors. Total mixer gain depends on the amplitude of the LO signal. Gain is maximized when quad transistors are alternately switched between fully on and completely off. During the on-state, the switching transistors behave as a cascode, which does not contribute significantly to noise. For higher LO amplitude the mixer performance is less dependent on the possible variation of LO amplitude [8].

The analyzed down-conversion double-balanced mixer is realized with HCBT integrated bipolar technology using a standard Gummel-Poon BJT transistor model. The HCBT model is physics based resulting in realistic transistor parameters. Simulations are conducted by Agilent's Advanced Design System (ADS) software. Circuit parts and parameters such as emitter resistance R_E, collector resistance R_C, bias current, impedance matching and the area factor of transistors are set in a way to achieve good linearity and overall mixer performance. Switching quad core is driven by the local oscillator signal that is connected to the LO input through LO buffer amplifier. The buffer amplifier provides single-ended to well-balanced differential drive conversion. Besides, it results better isolation between LO source and LO port of the mixer and it sets the proper DC voltage level for the LO port of the mixer. Circuit level optimization is done for mixer operation within the input frequency range of 1.5 GHz to 2.5 GHz. Intermediate frequency output (IF) is terminated with $Z_{load} = 2 \cdot R_C$ for the maximum output power.

Some of the most important mixer characteristics are conversion gain and IIP3 (*input third-order intercept point*). Conversion gain is defined as output (IF) and input (RF) power ratio. The IIP3 is most common linearity measure for the RF circuits. It is defined as input power at theoretical point where the amplitudes of the fundamental and intermodulation tones are equal.

Intermodulation tone is a result of the intermodulation distortion which occurs when two or more RF signals are present at the mixer input. For mixer operation most important is third-order intermodulation (IM3). It is defined as the amplitude ratio of the third-order intermodulation product to the intermediate frequency signal at the output. Value of IIP3 is inversely proportional to the IM3. Two signals at RF input with adjacent frequencies ω_1 and ω_2 are translated to the other frequency range by LO signal with ω_0 frequency. Usually ω_0, ω_1 and ω_2 are very close to each other and because of the mixer frequency translation, the unwanted third-order products occur at $\omega_0 - 2\omega_1 + \omega_2$ and $\omega_0 - 2\omega_2 + \omega_1$ frequencies that are hard to filter and they corrupt the desired signal. Plotted in a logarithmic scale, the power magnitude of the IM3 tone grows at the three times the rate at which the power magnitude of the fundamental increases [9]. The output power of fundamental and IM3 tone with respect to the available source RF power for the analyzed mixer are shown in Fig. 2. Intermediate frequency is kept constant at 45 MHz and LO frequency is swept from 1.5 GHz to 2.5 GHz. The RF frequency is such that the difference between LO and RF frequency remains the constant. It can be seen that power magnitude of the IM3 tone is smaller for higher frequency in the observed frequency range, while no significant difference in the fundamental tone output power is shown.

The obtained values of IIP3 and conversion gain are shown in Fig. 3. Input RF frequency is swept in a range from 1500 MHz to 2500 MHz and LO frequency is set to achieve IF frequency of 20 MHz, 45 MHz and 200 MHz respectively. Distortion simulations require two tones at the RF input and the used tone spacing is 200 kHz. It can be seen that linearity and conversion gain are larger for smaller IF frequency. For the observed frequency range, higher IIP3 and smaller conversion gain are achieved for higher frequency. Power values of the sources are -30 dBm for RF power source and 0 dBm for the LO power source which are the typical values.

III. Differential Amplifier Distortion

After the circuit level intermodulation distortion optimization, the one on the lower level is conducted. This is necessary because of the high complexity of the

distortion analysis in RF systems. The transistor parameters impact on distortion is analyzed on differential amplifier. Due to the flexibility of HCBT technology, the range of the parameters variations is realistic and achievable by the fabrication process. The analyzed parameters are:

- R_e – emitter resistance
- R_b – zero-bias base resistance
- R_c – collector resistance
- C_{je} – base-emitter zero-bias junction capacitance
- C_{jc} – base-collector zero-bias junction capacitance

These are the standard parameters of the Gummel-Poon's bipolar transistor model. Default values of the swept parameters for the unit transistor with area factor 1 are: R_e=60 Ω, R_b=400 Ω, R_c=1100 Ω, C_{je}=1.4 fF and C_{jc}=1.6 fF. The varied values of the R_e parameter are in range from 50 Ω to 200 Ω, for R_b from 150 Ω to 500 Ω and for R_c parameter from 400 Ω to 1600 Ω. Capacitance values of C_{je} and C_{jc} parameters are swept in range from 0.5 fF to 2.5 fF. By changing the C_{je} parameter, the base-emitter capacitance C_π is also changing, since:

$$C_\pi = g_m \tau_F + 2C_{je} \tag{1}$$

where τ_F is forward transit time, $g_m\tau_F$ is diffusion and $2C_{je}$ junction capacitance. The C_{jc} parameter changes the total base-collector junction capacitance given by:

$$C_\mu = C_{jc} / (1 + V_{CB} / V_{jc})^{M_{jc}}, \tag{2}$$

where V_{jc} and M_{jc} are base-collector junction built-in potential and exponential factor respectively. The bipolar transistors in the examined differential amplifier are set in the identical operating point as the transistors in the mixer transconductance stage. Similar circuit resistances are used.

The exponential nature of bipolar transistor transfer characteristic is the main cause of nonlinearity. Third-order nonlinearity results in the third-order intermodulation IM3 and also changes the amplitude of the fundamental tone. The effect is that third-order nonlinearity can change the gain, known as gain compression [8]. For the nonlinear transfer function, approximated by the series expansion of power terms:

$$s_0 = a_1 s_i + a_2 s_i^2 + a_3 s_i^3 + \ldots \tag{3}$$

where s_i is two tone input, the third-order intermodulation term IM3 can be expressed by:

$$IM3 = \frac{3}{4}\frac{a_3}{a_1} S_i^2, \tag{4}$$

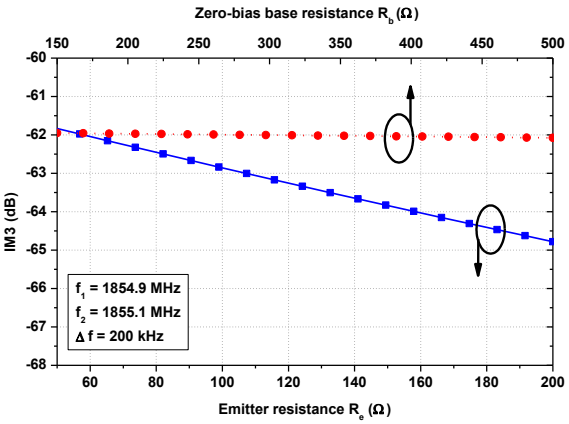

Figure 4. Simulated differential amplifier third-order intermodulation distortion (IM3) versus R_e and R_b resistance

where S_i is amplitude of the two input tones [8]. Similar expression is valid for Volterra series expansion, where a_1 and a_3 are Volterra series coefficients [1]. Transfer function (3) for the bipolar transistor in differential amplifier is:

$$i_c = a_1 v_s + a_2 v_s^2 + a_3 v_s^3 + \ldots \tag{5}$$

where v_s is AC source voltage, a_1 is equal to g_m, $a_2 = g_m^2/2I_C$ and $a_3 = g_m^3/6I_C^2$ [8].

The use of feedback reduces the distortion and increases linearity in the system, but it decreases gain. The feedback senses the output current and feeds back the input voltage. Commonly used feedback is emitter degeneration resistance R_E. The signal source resistance R_S increases linearity, but its influence is reduced by factor β in comparison to R_E [8]. By the use of emitter degeneration and signal source resistance in differential amplifier expansion coefficients take the form:

$$b_1 = \frac{a_1}{1 + a_1 f}, \quad b_3 = \frac{a_3(1 + a_1 f) - 2a_2^2 f}{(1 + a_1 f)^5}, \tag{6}$$

where $f = R_E + R_S/\beta$ [8]. The values of a_i coefficients in (6) are same as in (5). Increase of feedback factor f decreases the IM3 and increases the linearity because coefficient b_3 is decreasing faster than b_1 with the increase of feedback. The expressions (5) and (6) explain the harmonic balance (HB) simulations shown in Fig. 4. Bipolar transistor's internal R_e and R_b resistances have the similar influence on distortion as emitter and signal source resistances. Impacts of the R_e and R_b are superimposed to the R_E and R_S/β respectively. Higher values of R_e and R_b increase the feedback factor f reducing the coefficients b_3 and b_1 from (6) resulting in lower IM3. Impact of the resistance R_c is also simulated but its effect is negligible in comparison to the impact of R_e and R_b.

The detail Volterra series analysis, using different transistor models, is conducted in literature to derive coefficients for intermodulation prediction [2], [8], [10], [11]. Complexity is seen from [11]:

$$\left|\frac{a_3(\omega_1,\omega_1,-\omega_2)}{a_1(\omega_1)a_1(\omega_1)a_1(-\omega_2)}\right| = \frac{|\kappa(j\omega_0)|}{3I_Q^2}\cdot \frac{}{|1-\kappa(j\omega_1-j\omega_2)-1/2\cdot\kappa(2j\omega_1)|}, \quad (7)$$

where $\omega_0 = 2\omega_1 - \omega_2$. The κ is given by [11]:

$$\kappa(j\omega) = \frac{1+j\omega C_{je}Z(j\omega)}{Z_e(j\omega)+\frac{V_T}{I_Q}+Z(j\omega)j\omega(\tau_F+\frac{C_{je}V_T}{I_Q})}\cdot\frac{V_T}{I_Q}, \quad (8)$$

where $Z_e(j\omega)$ is emitter impedance, $Z(j\omega)$ is sum of emitter and base impedance and I_Q is DC operating current. Transistor model used for deriving (7) and (8) neglects the base-collector junction capacitance that is simplifying analysis to some extent. Capacitance influence on distortion strongly depends on operating frequency and the best performance can be obtained when the unity current gain frequency (f_T) versus collector current curve has the mildest slope which is often near peak f_T [2]. Near that point, cancellation effect can occur. Differential amplifier with inductive degeneration is more linear then that with resistive degeneration [10].

The HB simulations of transistor parameters C_{je} and C_{jc} influence on the distortion in differential amplifier show a little effect. Stronger influence of capacitances is present in the switching quad differential pair. This part of mixer performs a highly nonlinear function running in large signal mode. When the quad transistor is conducting it acts like common base stage amplifier. According to [11], [12], distortion is approximately equal to the sum of the distortions created by two mechanisms. First is low current mechanism where the transition time is very short and distortion mainly depends on C_{je} through $C_{je}V_T/I_Q$. The second mechanism is high current density mechanism where transition time when the all transistors are switched on is increased. Voltage drop on the parasitic base resistance R_b is not negligible and it generates distortion proportional to R_bI_Q/V_T [12]. With definition of current density factor as [11]:

$$K = R_bI_Q/V_T\cdot\sqrt{\tau_F/R_bC_{je}}, \quad (9)$$

distortion is function of K and LO power and has two minima. First occurs at very low current density where the noise and gain performance are poor and the second occurs for the K factor between 5 and 12, depending on LO power level [11]. The area factor of transistors in switching quad is such that gives K factor around the values providing possibility to achieve that second minimum.

The base-collector capacitance C_μ is another cause of nonlinearity. Because of voltage dependence visible from (2), it creates a term that has impact on the a_1 and a_3 coefficients. Its influence on distortion is most commonly added to the influence of base-emitter capacitance [11] or it is neglected.

Simulations results of the overall mixer third-order intermodulation dependence on capacitances C_{je} and C_{jc} in switching quad transistors are shown in Fig 5. The C_{je} impact on distortion is negligible in this situation, while with the increase of C_{jc} parameter there is a small decrease of the IM3. Parameters are changed only in transistors of the switching quad of the mixer for three different operating frequencies.

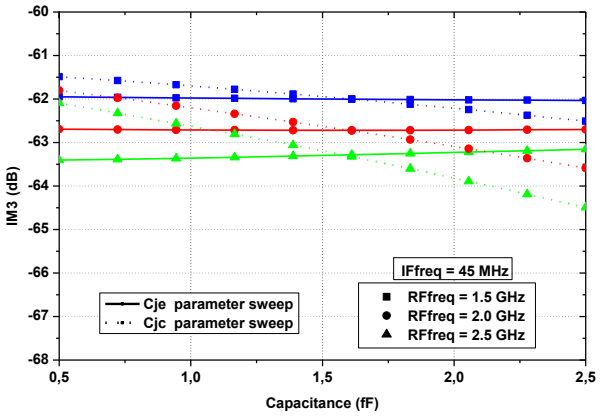

Figure 5. Simulated mixer third-order intermodulation (IM3) for mixer without LO buffer circuit versus C_{je} and C_{jc} capacitance in switching quad transistors for several RF frequencies, P(RF)= -30 dBm, P(LO)= 0 dBm

IV. MIXER DISTORTION

After the examination of differential amplifier, transistor parameter influence on intermodulation distortion is analyzed for the whole mixer. The bipolar transistor parameters influence on the total mixer distortion and gain is analyzed separately for the differential amplifier, switching quad and LO buffer. Besides that, simulations are conducted with and without the use of LO buffer. In the later case, the switching quad is driven by single-ended power source. Results for the case when LO buffer is included are better. The port-to-port isolation is better, IIP3 is higher for around 2 dBm and gain is smaller for 0.2 dB. The only disadvantage is that the mixer is more sensitive to the bipolar transistor parameter changes.

The waveform that drives the LO port of the mixer, i.e. at the output of LO buffer is not an ideal square wave, so this contributes to the mixer sensitivity to transistor parameter changes. Signal shape impacts the mixer linearity because it has finite rise and fall times. So, at some time, all transistors in switching quad will be in the on-state acting like an amplifier and degrading mixer linearity.

Main part of the buffer circuit is the differential amplifier, which allows single to differential signal conversion. Rise and fall time is limited by the RC time constant that consists of the buffer circuit output impedance and the mixer input impedance. Introducing emitter follower as the output stage of the buffer circuit gives better overall performance because it provides a low impedance to drive the mixer quad devices. Fall time is then limited by the amount of current discharging the quad capacitances [13].

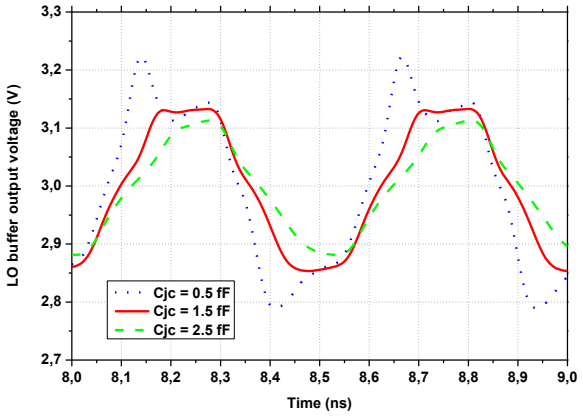

Figure 6. Simulated output LO buffer signal versus C_{jc} capacitance in emitter follower transistors in the buffer output stage

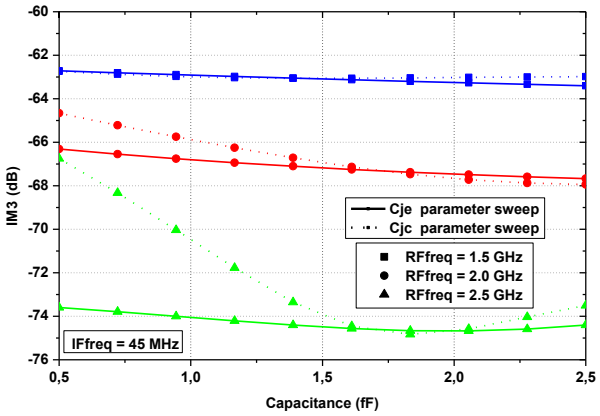

Figure 7. Simulated mixer third-order intermodulation (IM3) for mixer with LO buffer circuit versus C_{je} and C_{jc} capacitance in switching quad transistors for several RF frequencies, P(RF)=-30 dBm, P(LO)= 0 dBm

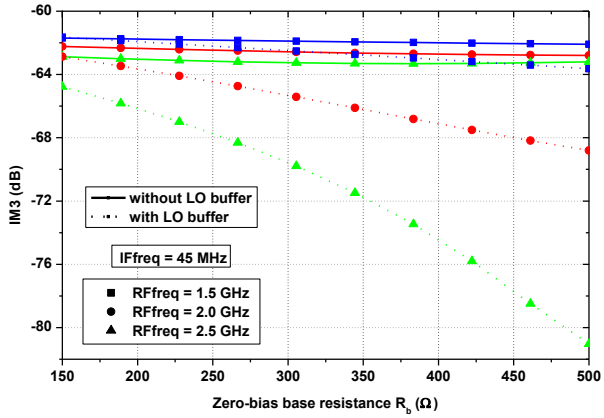

Figure 8. Simulated mixer third-order intermodulation (IM3) for mixer with and without LO buffer circuit versus R_b resistance in switching quad transistors for several RF frequencies, P(RF)=-30 dBm, P(LO)= 0 dBm

Simulations show that LO buffer output signal is the most sensitive to the C_{jc} parameter in buffer circuit emitter follower transistors. Time domain LO signal versus C_{jc} capacitance is shown in Fig 6. Output signal is closest to the ideal square wave for the C_{jc} = 1.5 fF and for that case the mixer IM3 is the lowest, leading to the highest IIP3. For the other two cases, IIP3 is smaller by 0.8 dBm (C_{jc} = 0.5 fF) and by 0.5 dBm (C_{jc} = 2.5 fF). Amplitude of the LO drive signal is decreasing with the increase of C_{jc} values leading to smaller gain. Gain is -3.1 dB for the smallest C_{jc} (0.5 fF) and -3.8 for the highest C_{jc} (2.5 fF) value.

Besides allowing a better overall performance, introducing LO buffer in the mixer circuit changes its sensitivity to the transistor parameters. This effect is obvious in Fig. 7, where the third-order intermodulation for mixer with LO buffer circuit versus capacitances in switching quad transistors is shown. The values of IM3 are smaller as compared to IM3 of the mixer without LO buffer leading to a better linearity. The IM3 differences in the simulated frequency range are greater in comparison to the case without LO buffer circuit implying a higher linearity sensitivity on operating frequency.

Impact of the R_b transistor parameter in switching quad transistors on the mixer distortion behavior for the mixer with and without LO buffer is shown in Fig. 8. Similar to the C_{jc} influence, IM3 values are reduced and frequency dependence is increased for the mixer with LO buffer.

Increase of the R_c in switching quad transistors causes the additional *IR* drop limiting the output voltage swing. At some point, transistors enter into saturation that causes the degradation of mixer linearity and gain performance. Therefore, the chosen range of R_c variation is below these values. Similarly, the *IR* drop due to increase of R_e of the switching quad transistors, causes the DC voltage variation at the emitter and the collector of the switching quad and differential amplifier transistors, respectively. However, the actual values of R_e are small enough causing no significant changes in mixer linearity and gain performance.

The differential amplifier impact on the total IIP3 and gain is similar as in section III. Values of the R_e and R_b parameters could be set in a way to increase linearity with no greater influence on the gain. Resistance R_c in differential amplifier transistors changes the internal collector DC voltage value. As stated earlier, this has no significant influence on mixer performance.

The base-emitter capacitance changes in differential amplifier through C_{je} parameter show no significant influence on distortion. In differential amplifier analysis C_{jc} shows small impact, but within the mixer distortion analysis its impact is increased and is added to the impact of base-emitter junction capacitance of switching quad transistors resulting in similar behavior of distortion.

Transistor parameter optimization is conducted after distortion analysis of main mixer parts in order to maximize the values of IIP3. Optimized transistor model for the emitter follower transistors in LO buffer circuit is the default one, which is not the case for the mixer core circuit. The C_{jc} parameter has the major impact in this case as stated earlier and for its default value of 1.6 fF distortion is the lowest. Linearity improvement is achieved by the increase of C_{jc}, C_{je} and R_b parameters in switching quad transistors. Optimized values are 2.2 fF, 2.0 fF and 500 Ω respectively. Transistors in differential amplifier contribute to the optimization through the increase of R_b and R_e parameters. Values of R_b and R_e used

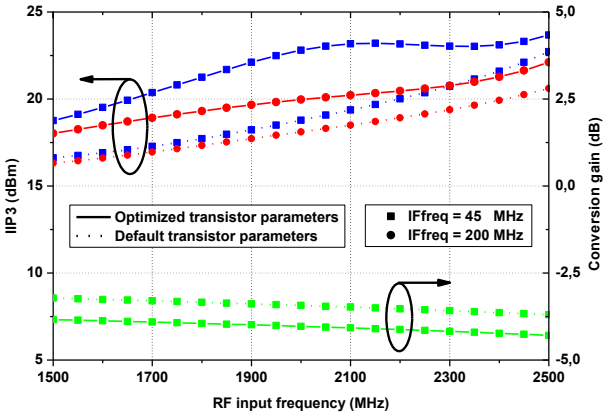

Figure 9. Simulated mixer third-order intercept point (IIP3) and conversion gain versus RF input frequency for the mixers with defualt and optimized transistor parameters for two intermediate frequencies (IF), P(RF)= -30 dBm, P(LO)= 0 dBm

in optimized model are 500 Ω and 150 Ω respectively. Although linearity is improved by increasing R_b, it would certainly have an impact on the noise performance of the circuit, which has to be taken into account in the overall mixer optimization. Summarizing effect of base-collector capacitance stated earlier is enhanced with increase of C_{jc} parameter in the optimized model. The used value for C_{jc} is 2.2 fF in differential amplifiers transistors.

Simulated results of the IIP3 and gain with use of optimized transistor models are shown in Fig. 9. The RF input frequency is swept in range from 1500 MHz to 2500 MHz and LO frequency is set to achieve IF output frequency of 45 and 200 MHz. For the 45 MHz output frequency case the achieved increase of IIP3 values is 4.5 dBm for some input frequencies. IIP3 increase is lower for the 200 MHz output frequency case. For both cases there is decrease in conversion gain of about 0.5 dB. Decrease of conversion gain for the 200 MHz is the same and it is not shown in Fig. 9.

V. CONLUSION

Impact of the HCBT transistor parameters on the characteristics of the double-balanced mixer is analyzed. Higher attention is given to parameter impact on linearity and gain. Main cause of nonlinearity in mixers is exponential nature of bipolar transistors. It could be reduced with use of emitter degeneration resistance and careful design at the circuit level.

Mixer parts show different linearity dependence on transistors parameters. Emitter resistance R_e in differential amplifier shows highest impact, while the impact of capacitances on linearity is present only when the entire mixer is analyzed. Switching quad simulations show greater impact when LO buffer circuit is included in analysis. Linearity is dependent on the shape of LO input signal and is better for signals that are closer to the ideal square wave. Parameters R_b and C_{jc} show the highest influence on linearity in switching quad transistors. In emitter follower transistors of the LO buffer, C_{jc} has the greater impact on the shape of the LO input signal.

Circuit level linearity optimization is much more important for the overall mixer linearity then the one taken on the transistor level. Nevertheless, understanding of linearity mechanisms in bipolar transistors could be used for additional optimization of overall mixer performance, as discussed in paper. Effects of that optimization could be incorporated in fabrication process resulting in better characteristics of mixers.

Confirmation of results of the simulations presented in this paper could be achieved through mixer fabrication process which is the next step of the research.

Abstract – Possibilities and principles for interconnection of CMOS ternary circuits and systems with binary common buses in digital circuits and systems are considered and described in the paper. Proposed are circuits with high-impedance output state for interconnection that perform signal conversion from ternary to binary CMOS digital system. General structure and general principle for design of such circuits are shown and described first. Then, the concrete circuit solutions are proposed and described. The circuits with one ternary input and the circuits with any number of ternary inputs are given and described. All proposed circuits were analyzed by computer simulations. All considerations, descriptions and conclusions were confirmed by simulation.

Key words: CMOS logic circuits and systems, Ternary circuits, Binary circuits, Interconnection circuits, High-impedance output state

I. INTRODUCTION

The binary digital systems and circuits are still dominantly used in practical applications. Possibilities and interest for implementation of so-called multiple-valued or MV digital systems and circuits are increased with development of VLSI technologies [1-3]. The greatest interest exists for ternary and quaternary MV circuits and systems [1-5]. The first developed and practically implemented have been ternary MV circuits and systems. Later, the greatest practical interest exists for research and application of quaternary logic systems and circuits.

The main reasons that the binary systems are mainly used are great investments into research, development, design and production of binary systems [1-5]. Great investments into realization of binary peripheral devices that consequently will be still very long period in use are also very important. So, there is a practical interest for development, implementation and application of so-called mixed digital systems [1,2,3].

Mixed MV systems use combination of binary logic circuits and MV logic circuits. One part of the system is realized using MV logic circuits and other part of the system is realized using binary logic circuits. MV logic circuits are also very often used for implementation of some functions inside binary digital system [1-3].

In the mixed MV systems it is needed to perform conversion of digital signals from binary form into appropriate MV form, and vice versa. Appropriate logic circuits for interconnection and conversion have to be used at places where is performed interconnection of binary parts and MV parts of the system [1,2].

The common buses are very often used methods for interconnection of functional units and circuits and for data transmission in the binary and mixed MV digital systems [1,2]. Connection to the common buses is implemented by the logic circuits with high-impedance output state. Due to the same reasons as in the binary systems, the common buses and the logic circuits with high-impedance output state are also used in ternary and mixed digital systems.

The advantages and reasons for application of the CMOS technology in implementation of binary digital systems and circuits are very well known. So, there is interest to develop and use CMOS ternary and mixed MV circuits and systems. All these good characteristics of CMOS technology should be also kept in the ternary and mixed logic systems and circuits.

Principles for implementation of CMOS logic circuits with high-impedance output state for conversion of ternary digital signals into binary digital signals are considered and described in the paper. The circuits are used for interconnection of ternary CMOS circuits and systems with binary common buses.

II. GENERAL STRUCTURE AND PRINCIPLE FOR CIRCUITS DESIGN

General structure and principle for design of logic circuits with high-impedance output state for interconnection of ternary and binary CMOS digital circuits and systems are shown in Fig.1.

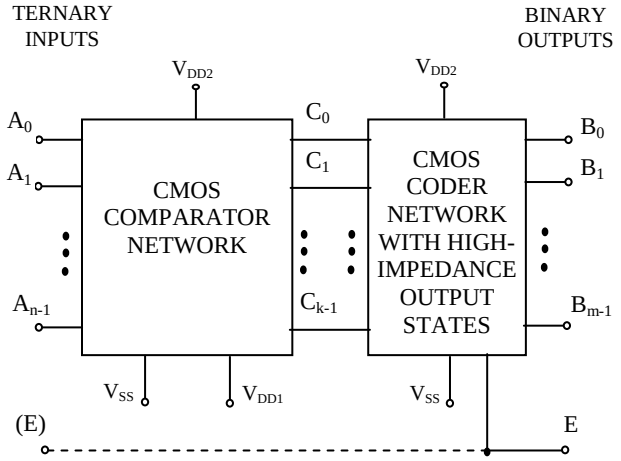

Fig.1. Structure and principle for realization of CMOS logic circuits for interconnection.

The shown structure consists of CMOS comparator network at the inputs and CMOS coder network with high-impedance output states at the outputs. There are *n* information ternary input logic signals and *m* binary output signals in the given structure. Also, there is one binary control input signal E for control of circuit output states. The CMOS comparator network is supplied by three supply voltages corresponding to ternary logic states and levels: V_{SS} (logic 0), V_{DD1} (logic 1) and V_{DD2} (logic 2). The output CMOS coder network is supplied by two supply voltages corresponding to binary states and levels: V_{SS} (logic 0) and V_{DD2} (logic 1). For one logic state (logic state 2) at the control input E the outputs of the circuit are enabled and the circuit operates as the standard CMOS logic circuit for ternary to binary signal conversion. For other logic state (logic state 0) at the control input E output CMOS transistors are turned off and the circuit outputs are in the high-impedance state. The control of circuit outputs can be performed from ternary signals side or from binary signals side.

A. *CMOS Comparator Network*

Ternary logic signals A_i are applied at the inputs of the comparator network. The binary logic signals C_i are obtained at the outputs. The network compares input ternary signals A_i with corresponding voltage thresholds and generates control signals C_i for CMOS coder network. Number of comparator network outputs depends on number of input ternary signals and number of output binary signals. Since here are used ternary input signals there are two voltage thresholds for comparison at any ternary input. The voltage thresholds are voltage values corresponding to the middle level between ternary logic levels:

$$V_{T1} = \frac{V_{SS} + V_{DD1}}{2}, \quad (1)$$

$$V_{T2} = \frac{V_{DD1} + V_{DD2}}{2}. \quad (2)$$

The lower voltage threshold is marked with V_{T1} and the higher voltage threshold is marked with V_{T2}. CMOS comparator network consists of CMOS voltage comparators at every input. There are more known solutions of CMOS voltage comparators.

B. CMOS Coder Network With High-Impedance Output States

The CMOS coder network with high-impedance output states is binary logic network. The task of the network is to generate output binary signals B_i depending of states at ternary inputs A_i and state at control input E. The network generates output binary signals B_i in accordance with state of binary signals C_i at the outputs of CMOS comparator network and state of control signal E. It can be designed and realized in the same way as standard CMOS coder networks and standard CMOS circuits with high-impedance output state.

III. PROPOSED INTERCONNECTION CIRCUITS

It can be designed and implemented more concrete solutions of such CMOS logic circuits for ternary to binary interconnection based on the shown and described structure from Fig.1.

A. *Circuits with one ternary input*

General scheme of circuit with one ternary input is shown in Fig.2. The circuit has two binary outputs (B_0 and B_1), one ternary information input (A) and one binary control input E. Two voltage comparator circuits (comparator 1 and comparator 2) are used at the input to compare input ternary signal A with voltage thresholds V_{T1} and V_{T2}. At the comparator outputs are generated binary signals C_0 and C_1. This signals are connected to the CMOS coder network with high-impedance output states that generates needed output binary signals. For every possible state at the ternary input A and binary input E it is obtained appropriate state at binary outputs B_0 and B_1.

CMOS Comparator Circuits

As the voltage comparator circuits (comparator 1 and comparator 2) can be used different known CMOS comparator solutions. That solutions have disadvantages in existing of static energy consumption and in need to generate referent voltages (comparison voltage thresholds

V_{T1} and V_{T2}). Here are proposed and shown solutions without such disadvantages, without static energy consumption and without need to generate comparison voltage thresholds V_{T1} and V_{T2}. Also, there is voltage histeresys in transfer characteristic and increased noise immunity in the circuits. The circuits perform voltage comparison and voltage level shifting at the output. The circuits are based on principles described in paper [6].

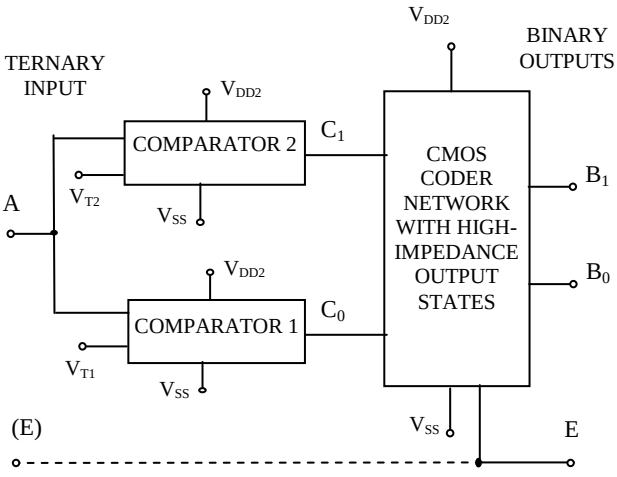

Fig.2. Circuit with one ternary input.

Proposed schemes of CMOS voltage comparators are shown in Fig.3. Comparator for comparison with lower voltage threshold V_{T1} (comparator 1) is shown in Fig.3a. Comparator for comparison with higher voltage threshold V_{T2} (comparator 2) is shown in Fig.3b.

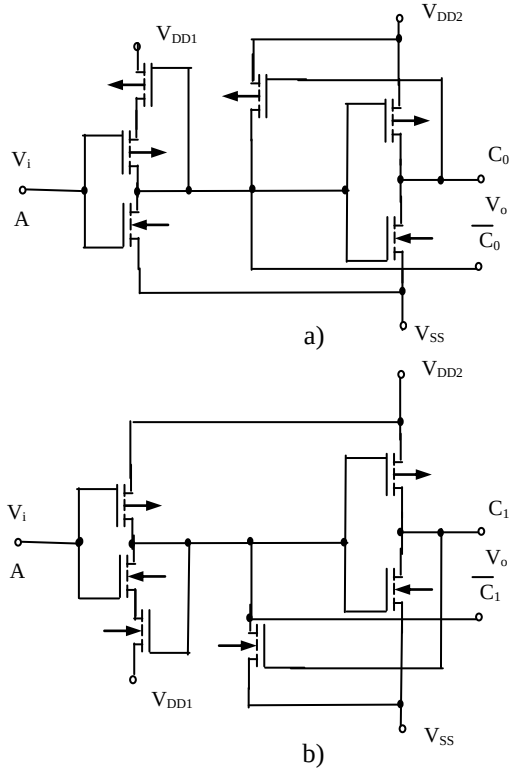

Fig.3. Proposed CMOS voltage comparators.

Operation of proposed CMOS voltage comparators was analyzed by PSpice simulations. Static voltage transfer characteristics of the voltage comparators are shown in Fig.4. By solid line is shown characteristic for comparator 1 (Fig.3a) and by dashed line is shown characteristic of comparator 2 (Fig.3b). In simulations were used technology parameters of one CMOS process [7] and supply voltages V_{SS}=0V, V_{DD1}=5V, V_{DD2}=10V. It can be seen that this circuits have histeresys in transfer characteristic and increased noise immunity. Value of voltage thresholds and voltage histeresys depend on supply voltages V_{SS}, V_{DD1}, V_{DD2} and on used CMOS transistors characteristics. It can be seen that the threshold voltage of the comparator 1 is approximately equal to V_{T1} and the threshold voltage of the comparator 2 is approximately equal to V_{T2}, that are given by equations (1) and (2).

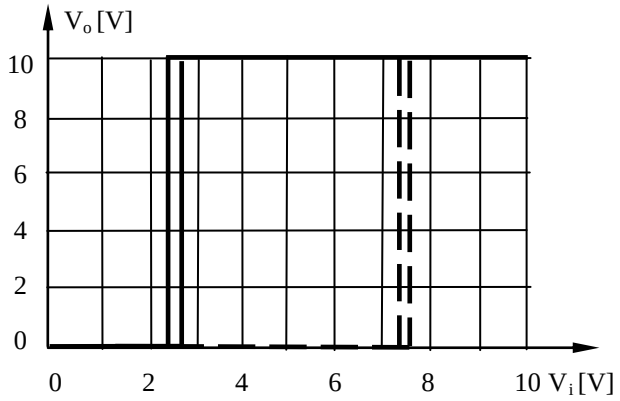

Fig.4. Static voltage transfer characteristics of proposed CMOS voltage comparator circuits.

Dynamic characteristics of proposed comparator circuits were also analyzed. Average delay time t_{da} of proposed circuits as a function of capacitive load C_L is shown in Fig.5. Average delay times of both circuits are approximately equal. The given results were obtained by PSpice simulations for the same conditions as for static transfer characteristics simulations.

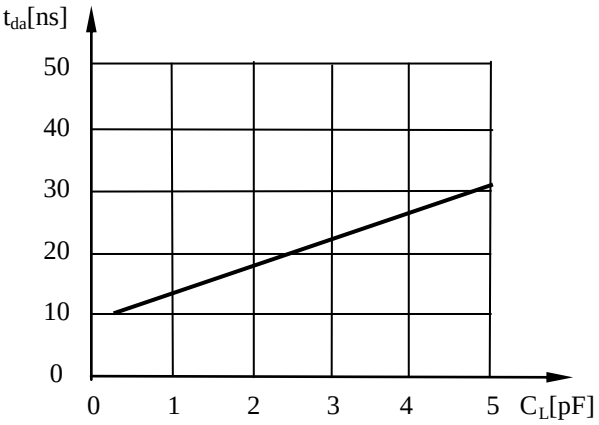

Fig.5. Average delay time of proposed CMOS voltage comparators as a function of capacitive load.

CMOS Coder Network With High-Impedance Output States

The CMOS coder network with high-impedance output states generates needed output binary signals B_0 and B_1 based on binary signals C_0 and C_1 and binary signal E. When is E=0 (voltage V_{SS}) the circuit outputs are disabled and in the high-impedance states. For E=2 (voltage V_{DD2}) binary outputs are enabled and output binary states depend on state at binary signals C_0 and C_1. It can be shown that for E=2 the output signals as a function of the input signals of the coder network are given by:

$$B_0 = \overline{C_1} \cdot C_0 = \overline{C_1 + \overline{C_0}}, \quad (3)$$

$$B_1 = C_1. \quad (4)$$

Since given voltage comparator circuits (Fig.3) have both outputs, noninverting and inverting output, for implementation of the CMOS coder network can be used both outputs to obtain simpler CMOS coder network.

The CMOS coder network has high-impedance output states. So, for implementation of the coder network can be used CMOS logic circuits with high-impedance output states (so called three-state CMOS circuits). The simplest method for implementation of coder network is to use CMOS three-state circuits at the outputs of coder network realized by standard CMOS logic circuits using equations (3) and (4). There are more ways to implement CMOS three-state circuits [8]. But, here is proposed other way to implement coder network that uses smaller number of CMOS transistors and has improved characteristics. It is based on integration of three-state logic into standard CMOS logic circuits. Here are proposed two such possible implementations.

Simple implementation of CMOS coder network with high-impedance output states is shown in Fig.6. It uses smaller number of CMOS transistors, but has greater delay times for greater capacitive loads.

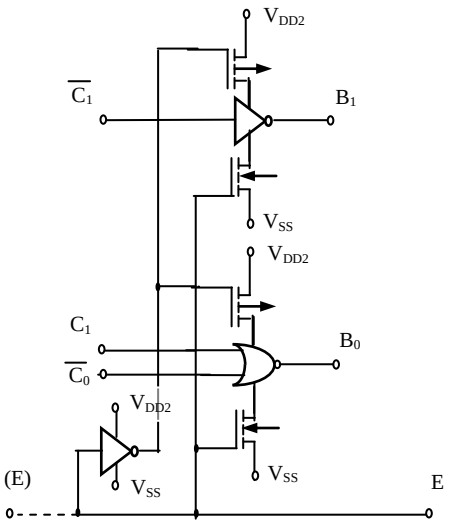

Fig.6. Simple CMOS decoder network with high-impedance output states.

Improved implementation of CMOS coder network with high-impedance output states is shown in Fig.7. The circuit uses greater number of CMOS transistors, but has smaller delay times for greater capacitive loads.

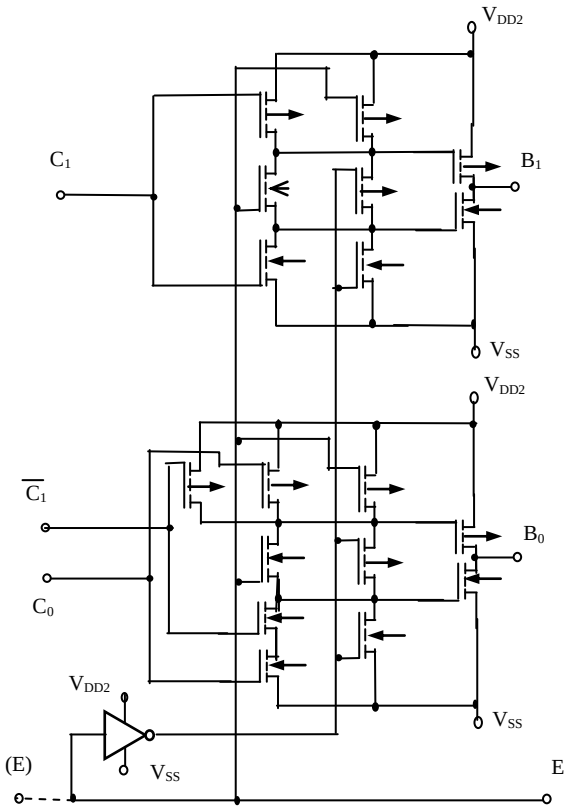

Fig.7. Improved CMOS decoder network with high-impedance output states

Circuit Simulation Results

The complete CMOS circuit with high-impedance output state and one ternary input for interconnection of ternary and binary circuits and systems was designed on the basis of described principles and given circuits. The circuit was analyzed by simulations. The output signals as a function of input signal changes when the outputs are enabled (E=2) obtained by PSpice simulation are shown in Fig.8. In the simulations were used the same technology parameters and the same supply voltages as in previous simulations. At the ternary input was applied slow changing signal that enables obtaining of all possible binary states at the outputs of the circuit, what can be seen in Fig.8. That is confirmation of proper operation of the circuit. Input ternary signal was marked by V_i, signal at binary output B_0 was marked by V_{o0} and signal at binary output B_1 was marked by V_{o1}.

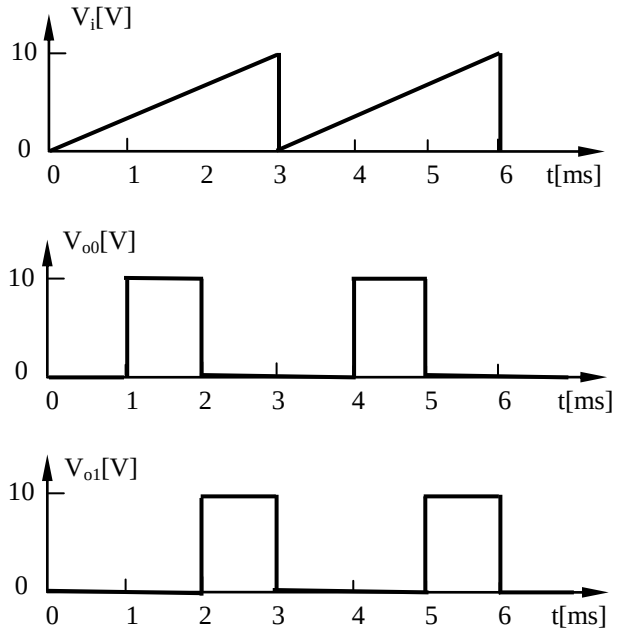

Fig.8. Output signals as a function of input signal changes when outputs are enabled for circuit with one ternary input.

B. Circuits With More Ternary Inputs

General structure and principle for implementation of circuits with more ternary inputs (with any number of ternary inputs) is shown in Fig.1. Implementation of concrete circuit includes determination of number of ternary inputs and number of binary outputs, design of input CMOS comparator network and design of output CMOS coder network with high-impedance output states.

Input CMOS comparator network can be implemented using same described voltage comparators from Fig.3. Two such comparators need to be used at every circuit input, according to principle from Fig.2.

Output CMOS coder network with high-impedance output states can be implemented according to same principles as for circuit with one ternary input. Based on binary signals from outputs of comparators and binary control signal E the network generates output binary signals

As an example of proposed and described principle, the proposed general scheme for implementation of circuit with two ternary inputs and four binary outputs is shown in Fig.9. At every of ternary inputs in Fig.9 are used two CMOS voltage comparators shown in Fig3.

CMOS output coder network with high-impedance output states generates output binary signals B_i on the basis of binary signals C_i from voltage comparators outputs and binary enable signal E. For E=0 the output binary signals B_i are disabled and in high-impedance state. When is E=2 the binary outputs B_i are enabled. Than, it can be shown that for circuit from Fig.9 with two ternary inputs the output signals for coder network are given by:

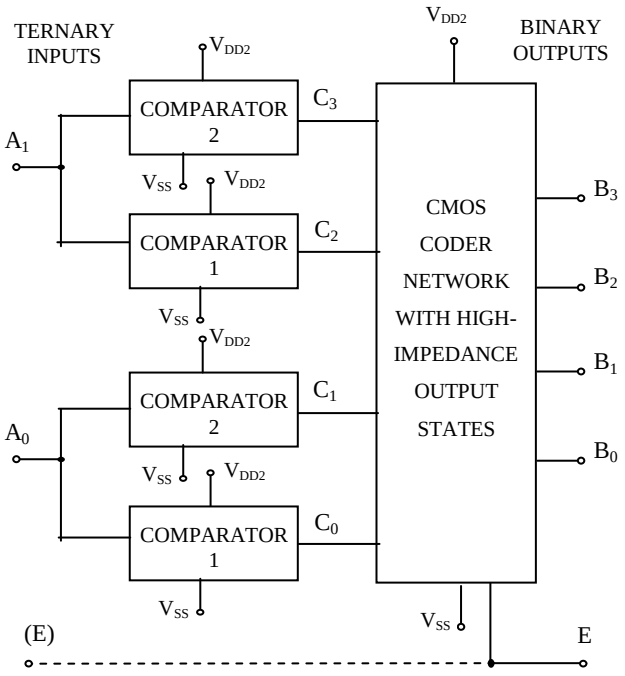

Fig.9. General scheme of circuit with two ternary inputs and four binary outputs.

$$B_0 = \overline{C_2}\cdot\overline{C_1}\cdot C_0 + \overline{C_3}\cdot C_2\cdot\overline{C_0} + \overline{C_3}\cdot C_2\cdot C_1 + C_3\cdot\overline{C_1}\cdot C_0, \quad (5)$$

$$B_1 = \overline{C_2}\cdot C_1 + C_2\cdot\overline{C_0} + C_3\cdot\overline{C_1}, \quad (6)$$

$$B_2 = \overline{C_3}\cdot C_2\cdot C_0 + C_3\cdot\overline{C_1}, \quad (7)$$

$$B_3 = C_3\cdot C_1. \quad (8)$$

As for circuit with one ternary input, for implementation of the coder network can be used CMOS logic circuits with high-impedance output states (so called three-state CMOS circuits). The simplest method is to use CMOS three-state circuits at the outputs of coder network realized by standard CMOS logic circuits using equations (5) to (8). Here is also used way to implement coder network that uses smaller number of CMOS transistors, has improved characteristics and is based on integration of three-state logic into standard CMOS logic circuits.

On the basis of proposed and described solutions it was designed complete scheme and circuit with two ternary inputs and four binary outputs. The circuit was in details analyzed using PSpice simulations. The simulations have confirmed proper operation of the circuit and all previous descriptions and considerations.

Described principles and scheme from Fig.9 enable to obtain such CMOS circuit for interconnection of ternary and binary digital circuits and systems with any number of ternary inputs and any number of binary outputs. Using concrete proposed solutions of CMOS comparators (Fig.3) and proposed way of comparators

application, as well as proposed ways for obtaining output CMOS coder circuit with high-impedance output states it is possible to obtain concrete schemes of such interconnection circuits with needed number of inputs and outputs.

IV. CONCLUSION

Very well known advantages of MV digital systems and great investments and experience in research, implementation, design and application of binary digital systems are the main reasons for increased interest for usage of mixed digital systems. Practically great interest exists for mixed MV systems where are used ternary and binary parts of the system. That requires practical application and usage of appropriate logic circuits for interconnection of ternary and binary parts of digital systems.

General structure and principles of implementation and design of CMOS circuits with high-impedance output states for interconnection of ternary and binary CMOS digital circuits and systems using common buses that are proposed in the paper are clear and relatively simple. Obtained circuits for interconnection are logic circuits without static power consumption (if we neglect MOS transistors leakage currents). Also, it is not needed to generate two referent voltages for comparison, but characteristics of standard CMOS inverters are used. It was achieved using proposed CMOS voltage comparators. Two proposed ways for design of CMOS coder network with high-impedance output states give possibility to implement circuits adopted to concrete working conditions at the place of circuit application. The circuits obtained using simple CMOS coder network, comparing with circuits using improved coder network, use less number of transistors. But, such circuits have greater propagation delay times for greater capacitive loads. The circuits obtained using improved CMOS coder network, comparing with circuits using simple coder network, use greater number of transistors. But, such circuits have smaller propagation delay times for greater capacitive loads.

Principles and elements used in realization of circuits with one ternary input are also used in realization of circuits with more ternary inputs (with any number of ternary inputs). The same pair of voltage comparators is used for every new ternary input. Output coder network with high-impedance output states is implemented on same principle as for circuits with one ternary input, but is more complex and has more inputs and outputs.

Proposed and described circuits are suitable for interconnection of ternary and binary circuits and subsystems inside of CMOS VLSI monolithic integrated circuits. Also, the circuits can be used as output circuits of monolithic CMOS integrated circuits or as separate CMOS integrated circuits for interconnection with smaller scale of integration.

To be possible to compare results of simulations and analysis with earlier obtained results for some other circuits in simulations were used parameters of one older CMOS technology process.

Abstract – High-gain charge pumps use MOS switches to rearrange the topology of the circuit in the adjacent half periods of the clock signals, which enables the charge pump circuit to achieve high output voltage. The MOS switches must be adequately controlled to enable fast charge transfer while turned "on" and to prevent leakage current while in the "off" state. This paper presents the limitations of the Cascode Voltage Switch Logic (CVSL) circuit as a control circuit for MOS switches. The operation of the CVSL driver is discussed and the negative effects of the capacitive load associated with the CVSL output node are analyzed.

I. INTRODUCTION

Majority of the charge pump designs used today follow the topology approach of the Dickson charge pump [1]. There are numerous variations that improve the performance of the original Dickson charge pump. For the integrated circuit implementation, the most significant aspects of the Dickson charge pump that need to be improved are the effects imposed by the transistor threshold voltage variation due to the body effect.

The well known designs that solve this problem are the bootstrap charge pump [2] and the CTS (Charge Transfer Switches) charge pump [3]. Similar approach, which minimizes the effects of the threshold voltage and the body effect, uses a charge pump with high amplitude clock signals [4]. All mentioned charge pump topologies are based on the Dickson charge pump and their voltage gain (output voltage vs. input voltage ratio) follows the arithmetic progression. The ideal gain of Dickson-based charge pumps corresponds to the *N*th number of the arithmetic progression for a charge pump with *N* stages.

Other charge pump topologies with the voltage gain higher than Dickson-based charge pumps often have a common problem with the control of the MOS switches used for the interconnection between the adjacent stages of the charge pump.

In the second chapter, the MOS driving problem is explained on the heap charge pump example. The third chapter presents the CVSL driver circuit and the simulation results of the charge pump performance with the CVSL circuit are given in chapter 4. Mathematical formulation of the simulated results and their comparison is presented in chapter 5, followed by the conclusion.

This work was supported by the Ministry of Science, Education and Sports of the Republic of Croatia under project 165-0361630-3049.

II. MOS SWITCHES DRIVING PROBLEM

The heap charge pump [5] and high-gain charge pumps, such as exponential-gain [6] and Fibonacci charge pump [7] are good examples for the analysis of the switching problem. Fig. 1 shows the heap charge pump, and Fig. 2 the voltage waveforms on the charge pump nodes marked 1, 2 and 3 in Fig. 1.

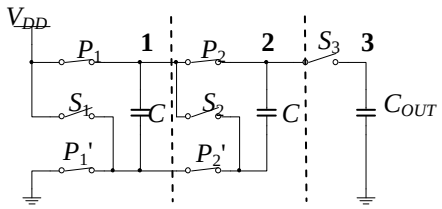

Figure 1. Heap charge pump.

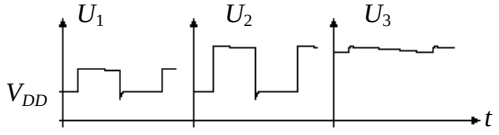

Figure 2. Voltage waveforms on charge pump nodes

The heap or serial-parallel charge pump has the voltage gain equal to the voltage gain of the Dickson charge pump, but its topology has the same transistor driving problem as the high-gain charge pumps, e.g. the exponential-gain and Fibonacci charge pump circuits. The transistor driving problem is explained in detail on the heap charge pump example.

Fig. 1. shows the heap charge pump with two stages. Each stage consists of one capacitor and three MOS switches. The operation of the heap charge pump can be divided in two phases. In the first phase, all capacitors are simultaneously charged during the first half-period of the clock signal while the switches P_i and P_i' (i = 1..N) are

closed and switches S_i opened. During the next half-period (switches P_i and P_i' are opened and switches S_i closed) all capacitors are connected in series and they are charging the output capacitance C_{OUT}. Besides the influence of the parasitics, the designer must solve the problem of driving MOS switches. Most of the charge pumps are designed using NMOS transistors because they provide higher current capabilities for the same surface area in comparison to PMOS transistors. With all switches being implemented by NMOS devices, the proper operation of P_i and P_i' switches is not a problem since all P_i switches can be diode-connected transistors and all P_i' switches have source potential equal to zero while closed. Therefore, the supply voltage V_{DD} level is sufficient to fully close the switch.

In the opposite cycle of the charge pump operation while the P_i switches are open, the source potential of the transistors rises with each stage and with the gate potential equal to zero, each P_i transistor is in non-conductive state with negative U_{GS} voltage. The problem occurs while driving S_i switches. During time interval in which P_i and P_i' switches are opened, switches S_i must be closed. If that is the case, then the source voltage of each S_i switch is positive and it rises in later stages. For the S_i switches to be in conductive state, the gate potential of each transistor must be higher than the source potential. On the other hand, to successfully cancel out the effects of the threshold voltage, the gate potential must be higher than the drain potential for at least the threshold voltage. With the positive source potential, body effect takes place and the required gate potential must be even higher due to the threshold voltage increase.

In the opposite period of the clock signal, in which S_i switches must be opened, all sources are on the ground potential, thus the gate potential must also be set to the ground potential for the transistor to turn off. This requires a gate voltage swing which must be significantly higher than the amplitude of the clock signal.

The same problem is present when driving the switches in the exponential-gain and Fibonacci charge pump. Both charge pumps have the voltage gain higher than Dickson charge pump and they follow exponential and Fibonacci progression for exponential-gain and Fibonacci charge pump, respectively.

III. CASCODE VOLTAGE SWITCH LOGIC (CVSL) DRIVER

First published in 1984, the CVSL circuit is presented as a member of the differential CMOS logic family [8] and is shown in Figure 3.

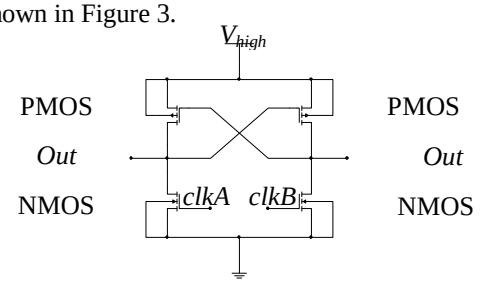

Figure 3. Cascode Voltage Switch Logic Circuit.

In the reference [9] a basic CVSL circuit is presented as a voltage level converter and as such it will be used in this work. The CVSL circuit can convert a low-amplitude clock signal into a high-amplitude clock signal. In the previous chapter it is shown that the gate voltage swing of the MOS switches must span from 0 V to the output voltage level so that they can be fully turned on in one half-cycle of the clock signal, and fully turned off in the next half-cycle. To achieve that, the CVSL must be supplied from the highest potential in the charge pump circuit, which is the voltage across the output capacitor.

Figure 3. shows the schematic of the CVSL circuit which consists of two PMOS and two NMOS transistors. Low amplitude clock signals are connected to the inputs marked as *clkA* and *clkB*. The clock signals must be non-overlapping to prevent extra charge leakage. Particularly, with overlapped clock signals in the time intervals when both *clkA* and *clkB* are in high state, both NMOS transistors are conducting. With the gates of the PMOS transistors pulled down to the ground potential through conductive NMOS transistors, they are diode connected and that way a conductive path is created between supply voltage and ground.

To convert a low-amplitude clock into a high-amplitude clock, a DC high voltage source is needed. This DC high voltage source is the output voltage of the charge pump. If a conductive path is created between the high voltage source and ground due to overlapping clock signals, the output capacitor voltage will drop significantly as the charge is being depleted.

By introducing the CVSL circuit into the charge pump topology, an extra care must be taken during the layout to prevent latch-up effect. The latch-up is combined SCR-type effect that can occur due to parasitic PNP and NPN bipolar transistors that are a part of a standard CMOS technology [4]. Even though the latch-up is more likely to occur on I/O interface of the integrated circuit, it can also occur here because of high voltage swing on the CVSL driver output. Each CMOS technology provides guidelines to reduce the possibility of the latch-up occurrence. With the guard ring around PMOS transistors and minimal distance between the *p* and *n* diffusion the possibility of the latch-up effect is kept minimal. While switching between high and low state of the clock signal, there is a short time interval in which both PMOS and NMOS device are conductive. To prevent large charge losses from the output capacitor PMOS devices have to be small, i.e. their widths have to be small.

IV. SIMULATION RESULTS

To show the impact of the PMOS transistor dimensions on the CVSL performance, SPICE simulations are carried out. Two parameters are of the interest when the implementation in the charge pump circuits is considered: the maximal operating frequency and the charge consumption under capacitive load.

With the constant NMOS length L_n = 0.5 um and width W_n = 10 um, the PMOS width is varied, while keeping the constant length L_p = 0.5 um, to evaluate the circuit performance. The simulations are done using the schematic in Figure 4.

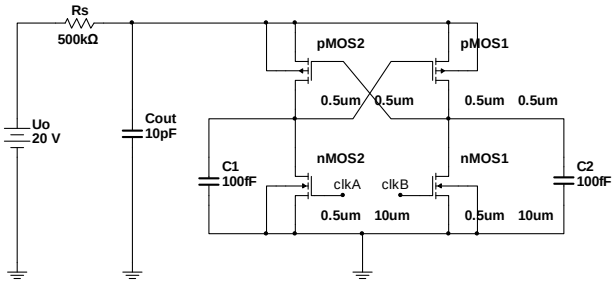

Figure 4. Circuit used for simulation.

The charge pump is modeled as the DC power supply U_0 with the internal resistance R_S and the output capacitor C_{out}. The resistance value of 500 kΩ corresponds to the equivalent series resistance of a 5-stage Dickson charge pump, each stage with a 10 pF capacitor and the operating frequency of 1 MHz. The equivalent resistance for any two-phase charge pump can be calculated from the following expression:

$$R_S = \frac{1}{f} \cdot \sum_{i=1}^{N} \frac{(a_{ci})^2}{C_i} \qquad (1)$$

where a_{ci} value is the ratio between charge transferred by *i*th stage and the charge transferred by the output stage of the charge pump [10]. The equivalent resistance also depends on the operating frequency *f*, the number of charge pump stages *N* and the capacitor *C* in each stage of the charge pump.

The operation of the circuit in Fig. 4 is simulated for several values of the PMOS width, and the results of the output voltages (voltage across the capacitor C_{out}) are given in Fig. 5.

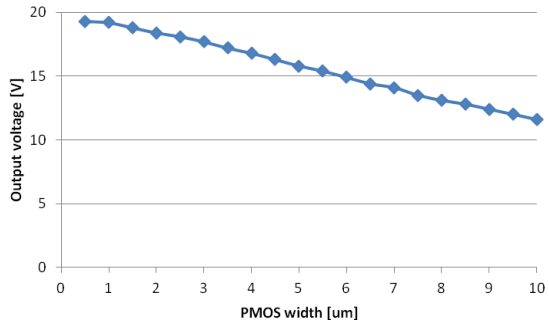

Figure 5. Output voltage for different PMOS width values (R_S = 500 kΩ, C_1 = C_2 = 10 fF, C_{OUT} = 10 pF).

A wider PMOS device has lower "on" resistance and it allows higher current peaks during switching between "high" and "low" states of the clock signals. These current peaks consume charge from the output capacitor and cause lower output voltage of the charge pump circuit.

The CVSL circuit is introduced into the charge pump design to serve as the driver circuit for the MOS switches. A number of MOS switches connected to the CVSL outputs, together with their connection paths form the capacitances C_1 and C_2 present at the CVSL outputs. These capacitances are charged to the output voltage value in one half-period of the clock signal and discharged in the next half-period. With a larger capacitance value, more charge is lost in each clock period. The effect of the capacitance size on the output voltage of the charge pump is shown in Fig. 6.

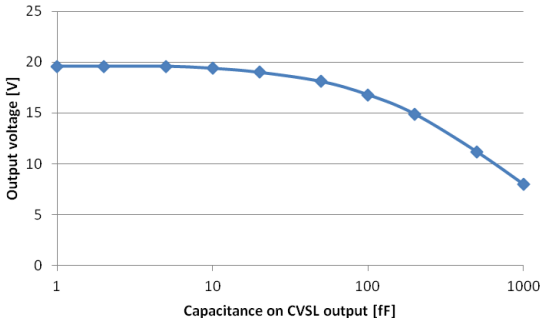

Figure 6. Output voltage vs. capacitance (C_1 = C_2) at CVSL output (R_S = 500 kΩ, C_{OUT} = 10 pF).

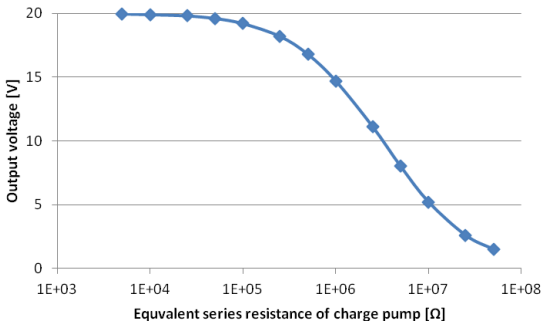

Figure 7. Output voltage for different series resistance of charge pump (C_1 = C_2 = 100 fF, C_{OUT} = 10 pF).

The equivalent series resistance of the charge pump varies by charge pump architecture, the number of the charge pump stages and the capacitance values. With higher series resistance, the charge consumption caused by the CVSL circuit is more pronounced, as shown in Fig. 7. With well chosen PMOS dimensions, the current peaks through CVSL driver are much smaller in comparison to the charge consumption due to the capacitance on the CVSL output.

V. MATHEMATICAL FORMULATION

The first order approximation of the charge pump output voltage with respect to the equivalent series resistance R_s and the capacitance C_{out} on the CVSL output can be evaluated using the circuit shown in Fig. 8.

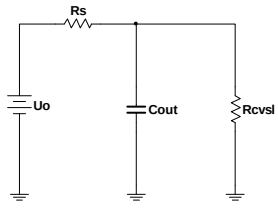

Figure 8. First order circuit model of the CVSL circuit.

The CVSL circuit connected to the output capacitor of the charge pump can be represented as a resistance R_{cvsl}, as shown in Fig. 8. This resistance models the charge consumption that occurs while the CVSL output is switching its states (current peaks) and the charge consumption due to the total capacitance of the CVSL outputs. The charge consumption during CVSL switching depends on the PMOS and NMOS dimensions and on the technology used. On the other hand, the charge that is consumed by the capacitance on the output of the CVSL circuit during each clock cycle can be easily modeled by the resistance. Each switched capacitor can be modeled as a resistor, as shown in Fig. 9.

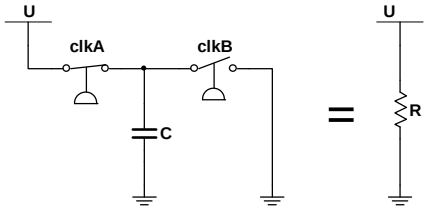

Figure 9. Switched capacitor modeled with the resistance *R*.

The value of the resistance used to model a switched capacitor at a given frequency is calculated by the following expression:

$$R_C = \frac{1}{C \cdot f} \tag{2}$$

Now, the capacitance associated with the CVSL output nodes can be represented as two parallel resistors, one for each output node. The value of R_{cvsl} (Fig. 8), neglecting the consumption due to current peaks, is given by (3),

$$R_{cvsl} = \frac{R_1 \cdot R_2}{R_1 + R_2} \tag{3}$$

where R_1 and R_2 are calculated using (2) for each CVSL output node.

To evaluate equivalent model of the CVSL driver (Fig. 8), a comparison between the simulation and circuit model is performed. Different values of the series resistance and capacitance at the CVSL output are used in comparison. The results are given in Fig. 10.

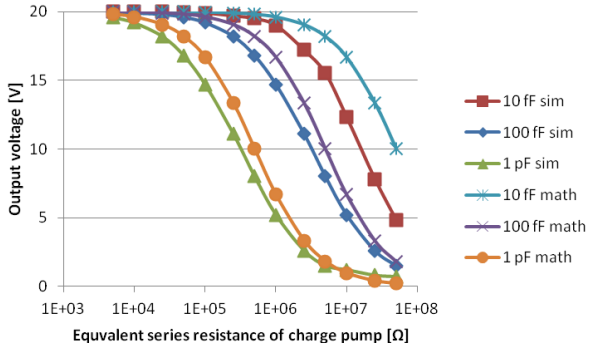

Figure 10. Comparison of simulation and circuit model.

VI. CONLUSION

The usage of the CVSL circuit for driving MOS switches in charge pump circuits is analyzed. The effects on the charge pump output voltage that are caused by the charge consumption of the CVSL circuit are simulated and mathematically formulated. The presented results show that the dimensions of the PMOS transistors in the CVSL circuit play a significant role on the charge pump performance. During the design of the charge pump with the CVSL circuit an extra care must be taken in the layout to keep the metal paths of the CVSL outputs as short as possible. This is necessary to decrease the parasitic capacitances of the metal paths connecting MOS switches with the CVSL outputs. It has been shown that the type of the used charge pump, the increase in the number of stages or the capacitance change in the charge pump stages affect the power consumption of the CVSL circuit.

Abstract - This paper focuses on an ASIC design for power MOSFET driver with an intelligent current driving technique which optimizes the performance and efficiency of driving single or more in parallel connected power MOSFETs. The efficient and robust driving of the power MOSFET gate is, besides the current driving techniques, also supported with the adjustable rise and fall times parameters of the driving signal. The design of the ASIC power MOSFET driver includes the implementation of safety functions which are essential for providing a higher level of robustness and reliability of the controlled power MOSFET transistor and power MOSFET system. The introduced mixed-signal ASIC is used as a single chip solution without any extra additional electronic components. This increases the integration density, reliability and reduces the costs of the power system.

Keywords: MOSFET driver, ASIC, current driving algorithm

I. INTRODUCTION

The power system designer's common target is to design a power electrical system that fulfills the demands of high performance level, optimized size and weight. In the power system, such as motor power controller used in various battery-powered driving systems, most of the volume is taken by capacitors. To reduce capacitors size and volume the switching frequency should be increased. But on the other hand the increased switching frequency would consequently increase the dynamic losses of the power switching elements. Besides the optimal power controller design layout, the major power losses come from the switching losses of the power switching elements such as power MOSFETs. The power losses could be reduced by selecting better power MOSFET transistor but this would increase the cost. The operating switching frequencies of power MOSFET transistors used in motor controllers are relatively low and are usually in the range from several kHz up to 20kHz. The main reason for such low switching frequency is that a power MOSFET with extremely low on-resistance R_{DSon} has a large area of the transistor gate. Another way how to optimize the power controller overall power loss is to find the intelligent MOSFET gate driving algorithm that reduces switching power losses and respecting EMI limitations.

In this paper, an ASIC design for power MOSFET with an intelligent current driving algorithm is proposed. The intelligent algorithm reduces switching losses and supports programmable rise and fall times. The proposed ASIC driver also has a safety function without any additional electronic components. The paper presents an ASIC design and simulation results of implemented intelligent driver technique for power MOSFET transistors.

II. INTELLIGNET POWER ASIC DRIVER

A. Prior art solutions

Most switching applications realized with power MOSFET transistors require "hard" switching of ohmic-inductive loads which is also the case in motor controller applications. In the battery-powered electrical driving systems the motor controllers are used to transform a DC voltage to a three (or more) AC signals for driving the motor phase windings. The sine signals used for driving the asynchronous AC motor are in most of modern systems realized with PWM switching algorithm of power switches. The MOSFET transistors are used as controlled switches which form conductive current path from positive or negative battery terminal to the connected load. The motor controllers realized with power MOSFET transistor generally operate at relatively low voltages which can reach up to 120V. But to reach high power levels the phase current peaks through windings can reach 500A. To achieve such high current densities the power module realization requires the power MOSFET transistors to be connected in parallel. Higher number of parallel connected MOSFETs enables higher current capabilities, high robustness and lower operating temperature. But on the other hand, because of increased gate capacitance, driving is more challenging.

The MOSFET transistor power losses can be divided in static and dynamic losses. The sources of static losses are power MOSFET characteristics where channel resistance (R_{DSon}) and intrinsic forward diode voltage (V_{DS}) are dominant contributors. The dynamic power losses are the losses generated while power MOSFET is switched on and off.

The primary task of the power MOSFET gate driver is to provide enough energy for effective and fast switching. Most of power MOSFET gate drivers are realized as classic IC voltage drivers. Such IC voltage drivers are designed as buffers which have higher power capabilities required for fast power MOSFET switching. More detailed description of the typical IC voltage drivers can be found in the literature [1], [2].

To optimize power MOSFET transistor instead of forcing voltage to the gate an current output is introduced allowing gate voltage shaping and consequently improve switching properties. In addition safety functions are

implemented such as temperature monitoring, undervoltage detection and overcurrent protection. Many of the above parameters are programmable.

B. ASIC structure

In Fig. 1 a block scheme of the proposed ASIC design is shown. The ASIC design can be practically divided in to three main parts: standard blocks, safety function

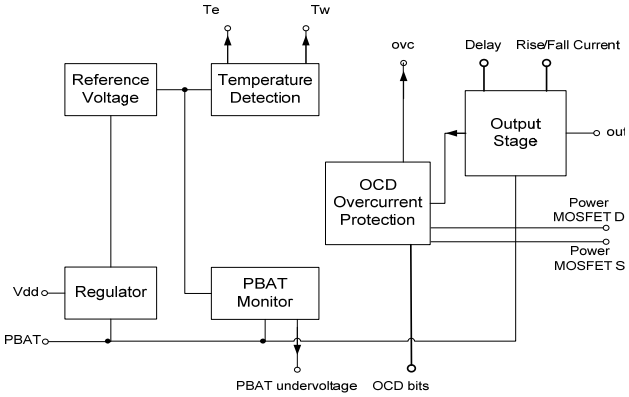

Figure 1. ASIC block diagram

blocks and intelligent driving algorithm block.

First part of the ASIC consists of relatively standard cells such as *Regulator* and *Reference Voltage*. Second part comprises the safety functionally: *Temperature Detection*, *PBAT monitor* and *Overcurrent Protection.* Those implemented safety features increase the driver reliability and system operation and also eliminate the use of additional external electronic components which would increase the driver circuit board complexity, reliability and cost.

The *Temperature Detection* block is used to monitor the ASIC die temperature. To avoid any ASIC malfunction and to minimize parasitic components of the connection paths the ASIC driver should be placed as close as possible to the power MOSFET transistor. From that we can conclude that both, ASIC and power MOSFET, have good thermal contact and consequently the same temperature. An important feature of the die temperature monitoring is the feedback information indicated by warning signal *Tw* and error signal *Te*. Both *Tw* and *Te* can be read out separately and be processed by

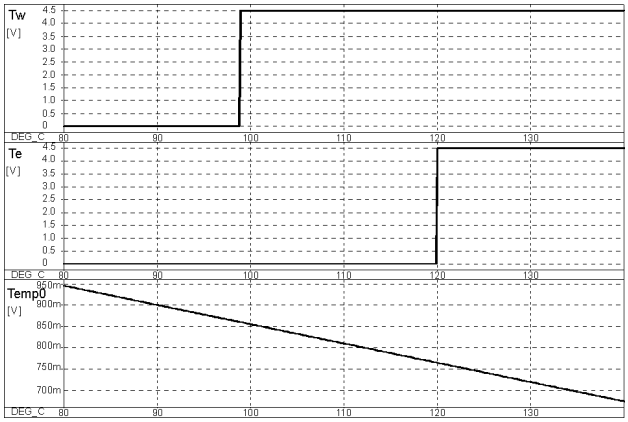

Figure 2. Temperature detection, signals *Tw*, *Te* and *Temp0*

system control unit. The temperature monitoring is based on comparison of internal generated reference voltage and temperature depended voltage named as *Temp0*. Internal voltage *Temp0* is linear proportional to the die temperature and it changes within range of -40ºC to +120ºC from 1.49V to 0.7V (-4.9mV/ ºC). To reset *Tw* the die temperature has to drop below 95ºC and in case of resetting *Te* the temperature should drop below 115ºC. The Fig. 2 show simulation results of *Temperature Detection* block signals, *Tw* as temperature warning set at 100ºC, *Te* as temperature error set when temperature of 120ºC is reached.

To prevent fatal power MOSFET transistor damages an *Overcurrent Protection* is implemented. The paper [3] introduces the method which monitors gate charge and discharge current with purpose to detect possible power switch malfunctions. The *Overcurrent Protection* bases on measuring the voltage drop between drain and source, V_{DS}, of the driven external power MOSFET transistor. The voltage V_{DS} is measured only during on state of the power MOSFET. The level of overcurrent protection is adjustable. When the adjusted current limit is reached the signal *ovc* goes high. The allowable level of the current of power MOSFET mainly depends on driven power MOSFET properties, especially by the MOSFET channel resistance R_{DSon}.

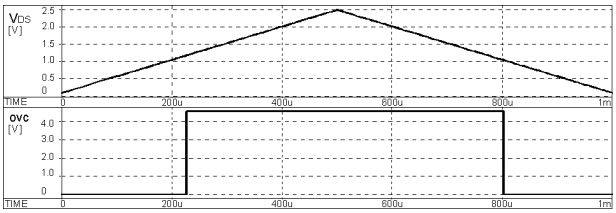

Figure 3. Overcurrent protection, signals V_{DS} and *ovc*

Especially for battery-powered system an important issue is to monitor the battery voltage V_{PBAT} to detect situations when voltage drops below certain level. The ASIC is designed to operate at supply voltages from 12V to 36V range. When the supply voltage drops below 10V then ASIC output *puv* is set high. This warning signal is cleared when the supply voltage rises above 11V.

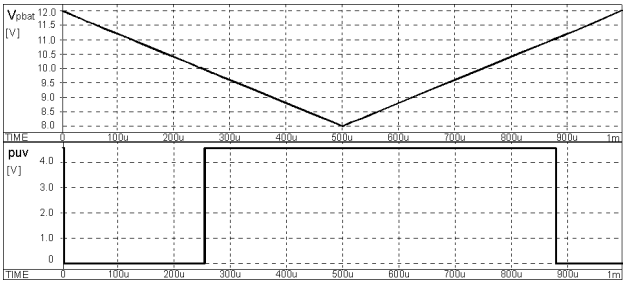

Figure 4. Undervoltage protection, signals *pbat* and *puv*

C. Intelligent driving algoritm

The intelligent current driving algorithm is implemented in the *Output Stage* block as shown in Fig. 5.

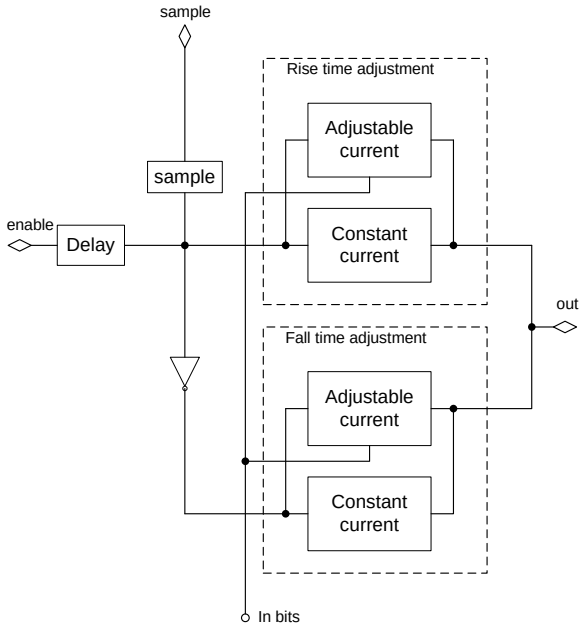

Figure 5. Rise time adjustment

Signal *enable* is used to turn on external power MOSFET transistor. With sub-circuit *Delay* only delay of the first front is done. This provides an ability to control so called "dead time". Dead time is defined as the time between two or more subsequent switching events. The control over dead time duration has a great importance in controller switching application for preventing any current cross-conduction between upper in lower switch and also to optimize the time of current flowing thru the freewheeling diode of the power MOSFET transistor. The delay can be set in nine steps. Nominal delay when all *delay* bits are '0' is 110ns, each step brings approximately 135ns of additional delay. At the end maximum adjustable delay is 1.1us. The set-up of *delay* bits depends on the electrical properties of the controlled external power MOSFET transistor(s) and end application where ASIC driver is used.

The power MOSFET transistor voltage drop V_{DS} sampling is performed as a constant delay at 1.5usec to avoid transient signal variations due to a current overshoot which would result in a wrong message *ovc*.

The *Output Stage* is divided into two individual sub-block separated to control the switching rise and fall time of the switching signal *out* connected to the power MOSFET gate as shown in Fig. 5 marked as "*Rise time adjustment"* and with *"Fall time adjustment"*. Each of sub-blocks consist of constant current and adjustable current source both controlled by signal *enable*.

The *Rise time adjustment* block is presented on Fig. 6. Signal *enable* is distributed to upper and lower part of the circuit. Upper half of the circuit shown on Fig. 6 controls the constant part of the *out* current which flows from *PBAT* to *out* node through PMOS transistor (4). The *enable* signal is also used to turn the transistor (1) on when switching the power MOSFET transistor gate is not required. To provide a constant voltage difference between gate and source node of PMOS transistors, regardless to *PBAT* voltage, a *LT* block is used.

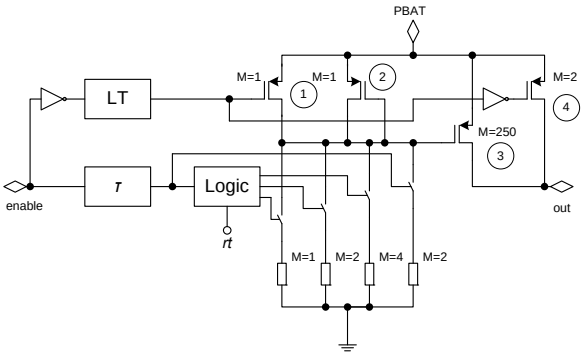

Figure 6. Rise time adjustment

More complex lower part circuit is used to generate current adjusted with *rt* bits. First, pulse generation block τ provides a high current at the beginning of the power MOSFET transistor switching on for time τ. The purpose of applying high current is to reach fast the Miller level from off state of the power MOSFET. When signal *enable* is set high the current through selected transistors, selected by *rt* bits, the output current I_{out} of the *out* start charging the Miller capacitance of the power MOSFET transistor.

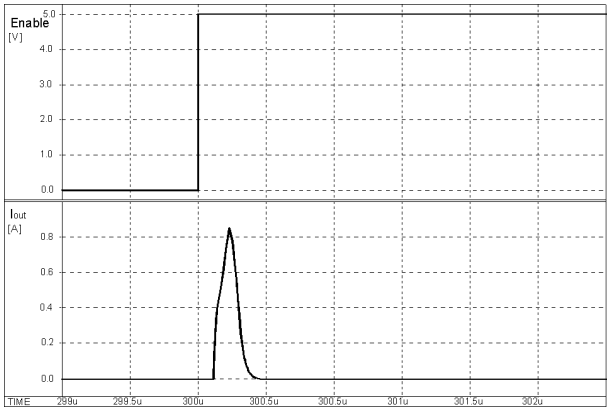

Figure 7. *Enable* and *Iout* output drive current at turn on

Both bit sets, *rt* and *ft*, are selected according to the switching properties of the controlled power MOSFET transistor(s) and also to the EMI requirements of the application. Fig. 7 presents signals *Enable* and output current I_{out} drive current at power MOSFET transistor turn on.

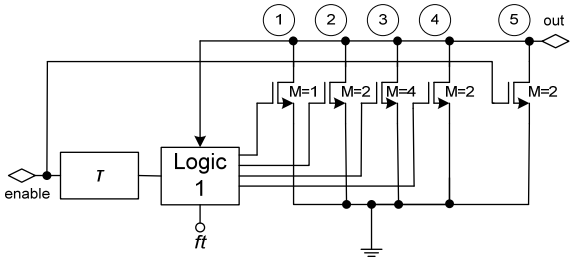

Figure 8. Fall time adjustment

The *Fall time adjustment* block is presented on Fig. 8 and is used to provide current when power MOSFET transistor will be turned off.

Block for pulse generation τ and *Logic1* have the same functionality as in the case described above. The constant part of the current provided for switching the power MOSFET transistor off to output *out* is generated with transistor (1). Transistors marked (2), (3) and (4) operate as different pull down current value regarding to the user selected adjustable *ft* bits. A special feature of the block *Logic1* is output voltage modulation regarding the voltage level on controlled power MOSFET transistor. At certain predetermined value the transistors (2), (3) and (4) turn off and consequently a different discharging current is generated. This is shown in Fig. 9.

Figure 9. Enable and I_{out} output drive current at turn off

This function provides two different discharging current slopes. Transistor (5) provides small current which discharge the remaining gate charge of the power MOSFET transistor until $V_{GS}=V_{out}$ equals 0V.

D. Measurement results

The ASIC has been prototyped in CMOS technology with 0.25µm minimum dimension and maximum breakdown voltages of 40V. The photolithography of the prototyped ASIC is shown in figure 10. The ASIC chip dimensions are (1612 x 1192) µm.

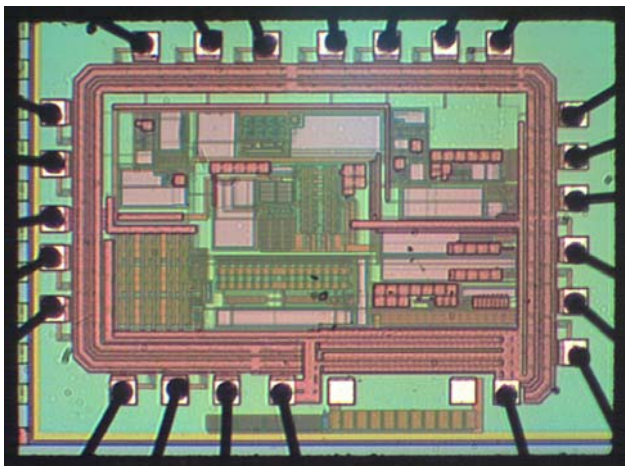

Figure 10. Photolitography of the ASIC prototype

Power consumption of the ASIC samples is 0.6mA without external load at voltage V_{PBAT}=12V. The current consumption of the ASIC driver depends on the load and also from the selected set-up of the *tr* and *tf* bits.

The measurement of the battery voltage level V_{PBAT} monitored with *puv* signal was also performed. The warning signal *puv* sets off when voltage V_{PBAT} drops below 11.0V and it sets on when V_{PBAT} reaches more then 10.0V

The temperature measurement results of the first prototyped ASIC sample are shown in Fig.11.

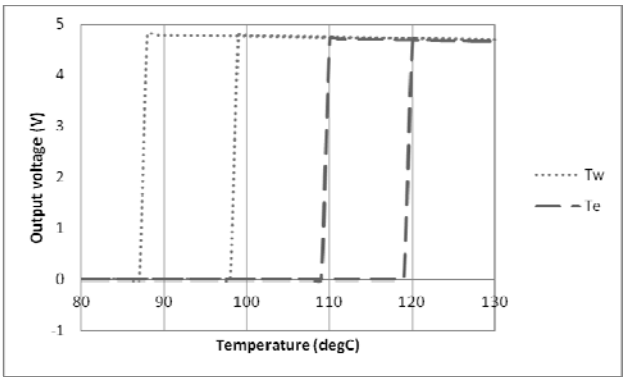

Figure 11. Temperature measurements with signals *Tw* and *Te*

The graph in Fig. 11 shows the temperature behavior of the warning signal *Tw* and temperature error signal *Te* versus ASIC die temperature. The signal *Tw* sets on when temperature reaches 99ºC and sets off when temperature drops below 87ºC. In case of temperature error signal *Te*, the *Te* sets on when temperature of 120ºC is exceeded and it clears when temperature of the ASIC drops below 109ºC.

TABLE I. MEASUREMENT RESULTS

delay (bits)	Time (ns)
000	350
001	430
010	575
011	670
100	780
101	885
110	970
111	1085

V_{PABT}=12V, C_L=10nF, T_{amb}=25ºC

Table 1 shows measurement results of the time delay versus different bit *delay* configurations. The maximal delay time duration can be set up to 1085ns and minimal to 350ns. The average bit step of the *delay* is 105ns.

III. CONLUSION

The paper introduces an ASIC design of intelligent driving algorithm for power MOSFET transistors. The proposed driver drives the gate of the MOSFET with controlled current and offers the user to adjust rising and falling times of gate charging/discharging. Safety function of temperature monitoring, overcurrent and undervoltage

are added. The ASIC has been prototyped and the measurement results agree with simulations.

Future work will be focused on the complete ASIC sample characterization. In addition we plan to implement ASIC in end application which would include power stage and perform measurements and analysis of the performance of the complete system.

ACKNOWLEDGMENT

The author wishes to thanks Slovenian Research Agency which financially supported this paper and also special gratitude to the project partner Iskra Avtoelektrika d.d and Center of Excellence NAMASTE.

The author also wishes to express gratitude to the laboratory personnel of the Laboratory for Microelectronics at the University of Ljubljana.

Reconfigurable Processor Architectures: Varieties and Representations

Damir Kirasic and Danko Basch,
University of Zagreb, Faculty of Electrical Engineering and Computing, Croatia

***Abstract*—Reconfigurable processors combine the speed of application specific integrated circuits (ASIC) and the universality of classical digital processors by means of adaptability to the currently executed code. There is a great number of varieties in today's reconfigurable processor architectures. Processor architectures can be specified in many ways. Architecture specifications are usually used during the architecture design phase and in software tools such as compilers and simulators. The aim of this paper is to propose various comparison criteria for reconfigurable processor architectures and to give an overview of the specification methods for them. The main contribution of this paper is a proposal of the new ontology-based representation of reconfigurable processor architectures.**

I. Introduction

Reconfigurable processors (RP) combine the speed of application specific integrated circuits (ASIC) and the universality of classical digital processors. ASIC circuits are the fastest way of processing digital data because they are pre-tailored for known functions. Classical processors spend a lot of time in fetching and decoding relatively small set of basic instructions.

The main difference between classical processors and reconfigurable processors is that RPs try to adjust their internal structure to the currently executed code. Classical processors have fixed, unchangeable structure while all RPs have some changeable, adjustable components. These changeable components are called *reconfigurable fabric* (RF).

The process of adjustment is called *reconfiguration* and its goal is to dynamically create ASIC-style logic that will perform required functions as fast as pre-tailored circuits. The speedup of execution in reconfigurable processors comes from the ability of RF to concurrently process input data and to work in a way similar to dataflow architectures.

The time needed for reconfiguration is relatively short and processor can switch quickly to different configurations even during the execution of the same program. Appropriate processor configuration can be determined at the phase of code compilation. In that case the compiler will usually insert reconfiguration procedures at the appropriate place in the generated machine code. Such reconfiguration is called a *static* reconfiguration. If the decision about reconfiguration is done during the runtime, reconfiguration is considered to be *dynamic*.

There is a great number of varieties in todays reconfigurable processor architectures. Architectures can differ significantly and it is not an easy task to compare them. For example, some architectures use fine-grained, bit-oriented components in the reconfigurable fabrics while others use word-oriented, coarse-grained components. Some architectures use an array of the same (homogeneous) processing elements while others use a mix of heterogeneous elements.

Fig. 1 shows a typical example of the coarse-grained architecture - Dynamically Reconfigurable Processor (DRP) [24] [32]. The DRP architecture has been developed at University of Zagreb, Faculty of Electrical Engineering and Computing. The architecture has 5 main components: sequential processor, main memory, DMA logic, control logic and a 2D array of coarse-grained processing elements. The functions of the processing elements and interconnection paths between them can be quickly and dynamically changed.

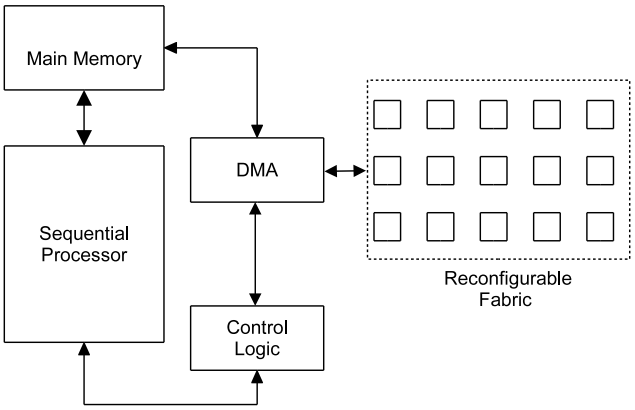

Fig. 1. Main components of the DRP architecture

The DRP architecture is similar to the HMP (Hybrid Micro-Parallel) type architecture [33] [7].

The first aim of this paper is to propose a methodology or set of criteria for comparing different reconfigurable processor architectures.

The second, and most important aim is to propose a novel methodology for describing processor architectures. The precise, unambiguous specification of the processor architecture, that will represent all the relevant details, is of great importance. Such description will be usually used in more than one environment: as a precise specification during the architecture design phase, as an input to the simulator tool and as a part of the compiling system.

The main contribution of this paper is a proposal of the ontology-based description for the reconfigurable processor architectures. In this work, the Web Ontology Language (OWL) [13] [16] is used as a declarative language for describing processor architectures.

The paper is organized as follows. Section 2 gives a brief overview of the related work in this area. Section 3 describes a list of the proposed comparison criteria. This section contains the table of a few existing architectures and their classification according to the proposed criteria. The OWL-based processor specification is described in section 4 and the conclusion remarks are given in the last section.

II. Related work

Reconfigurable processors are part of the research field that is called *reconfigurable computing* or sometimes *spatial computing*. The field of reconfigurable computing is roughly comprised of two main subfields: reconfigurable processor architectures (HW) and supporting software tools (SW).
The beginnings of the reconfigurable computing can be traced back to the 1960s in the work of Gerald Estrin [10] but probably the most important event in the history of reconfigurable computing was the appearance of the Field-Programmable Gate Arrays (FPGAs) in the 1980s. The FPGAs enabled fast development and prototyping that resulted in the fast advancement in the field that occurred in the middle of 1990s.

There is a great number of published papers in the field of reconfigurable computing. Here is the chronological list of some surveys published after the year 1999: [28] [14] [9] [29] [1] [6].

A. Classification criteria

All reconfigurable computing surveys try to define some set of classification criteria by which various architectures can be compared. Different approaches advocate different criteria. Here is the list of the most notable criteria with brief clarification.

- Granularity of RF: how complex are the basic logical units?
- Homogeneity/heterogeneity of the processing components in RF: are all basic units of the same type?
- Coupling between sequential processor and RF: bus connection; special on-chip connection, etc.
- The communication type between sequential processor and RF: master-slave or peer.
- Sequential processor and RF can/cannot work simultaneously.
- Geometry/topology of RF: 2-D, 1-D, mesh, hierarchy.
- Hierarchical organization of RF: basic logical units are grouped into ”stripes” which are grouped into ”pages” that form ”clusters” [23], etc.
- Interconnectivity of the processing components in RF: mesh, buses, switches.
- Homogeneous/heterogeneous interconnection architecture: various parts of RF hierarchy can have different interconnectivity types.
- Distribution of local memory and register files in the RF: basic logical units are with/without local registry files and/or local memory; they share the same memory.
- Reconfiguration and its associated configuration data can be defined for the whole RF (full reconfiguration) or only for the parts that have to be changed (partial reconfiguration).
- RF can support time-multiplexing (virtualization) of the available circuits: some tasks that require more RF than available can be accomplished by time-multiplexing.
- RF is able to execute: data intensive program kernels only or whole programs.
- The fault-tolerance capability: if some basic logical units have manufacturing defects, redundant units will be used.
- In the course-grained architectures, a basic element can be used as a routing element only, as a processing element only, or both.
- RF is optimized for: low power consumption; lowest possible area; fastest execution time; some mixture of the above.

B. Architecture description

Architecture description/specification is some kind of data that represents the details of the processor architecture. The purpose of this description is to define all relevant details of the architecture.

Many software tools that need architecture description do not even specify the methodology or data format used for architecture description. It usually means that the architecture is defined by some in-program data such as set of variables and/or program classes and structures. Hopefully some architecture features, such as a number of processing elements in the 2D array, are defined as parameters and can be changed.

The most common situation is to have some form of ”configuration” that is used as a description. For example, Trident [30] is a compiler tool for reconfigurable architectures that uses ”hierarchical hardware description to preserve modularity” and ”interface description files”. In Trident, fixed- and floating point algorithms are described by high-level language. This description is later translated into a circuit design.

Often, the description is saved as an XML document. DRESC architecture [19] [21] uses Modulo Routing Resource Graph (MRRG) to internally describe processing architecture. It is constructed from the ”architecture specification” that is defined as an XML document. A separate ”architecture parser” program will construct MRRG from the XML architecture specification.

Some authors advocate more complex form of descriptions. For example, the authors of [8] advocate a new ”high-level description formalism” to describe the architecture.

In fine-grained architectures usually the circuit layout is defined by hardware description languages such as Verilog or VHDL. For example, the HMP architecture [33] uses Verilog modules and the architecture is represented as a datapath graph [11].

III. Comparison criteria

A. The main criteria

The main reason for accepting certain criteria and to drop the others is universality. For example, if some criteria is applicable to fine-grained architectures only then it is not considered as the most important one. It is important to note that none of the above criteria is related to the execution speed or any kind of speed performance. It is beyond the scope of this paper to analyse performance aspects of various architectures.

According to our opinion there are six most important comparison criteria:

1) Granularity.
2) Geometry/Topology of RF.
3) Interconnectivity of reconfigurable components.
4) Homogeneity/Heterogeneity of reconfigurable components.

5) Coupling between sequential processor and RF.
6) Distribution of local memory in RF.

Here is the brief description of these criteria.

1) Granularity: The adaptability of reconfigurable fabric as a whole is achieved by defining the functionality of basic logical blocks and the interconnection paths. Basic logic units can be as simple as a small, bit-oriented lookup-table (LUT) or as big and complex as an 8-bit ALU or multiplier. The processor architecture that use simple logic units is called *fine-grained*. The architectures that are composed of complex logical blocks are named *coarse-grained* reconfigurable architectures (CGRA).

Middle-grained architecture are also possible. For example, the Tartan architecture [23] is considered to be a middle-grained. There is no clear border between types of architectures.

2) Topology: The most common topology for reconfigurable fabric is a two-dimensional array (2D). In case of coarse-grained, homogeneous system the RF is composed of the 2D array of processing elements that are all of the same type.

In order to reduce the ratio between interconnecting-type circuits and processing-type circuits some authors advocate one-dimensional topologies or some varieties of two- and one-dimensional geometries. Examples of the one-dimensional topology are Garp [15] and PipeRench [12].

3) Interconnectivity: Fig. 2 shows basic types of interconnectivity. In all these types the connection lines can be 1-bit wires or word-wide lines or buses. Also, in all types of interconnectivity there can be some hierarchical structure involved. For example, Tartan [23] has different interconnectivity architectures for different levels of circuits. For further discussion on interconnectivity and Network-on-Chip (NoC) topologies see for example [25] and [17].

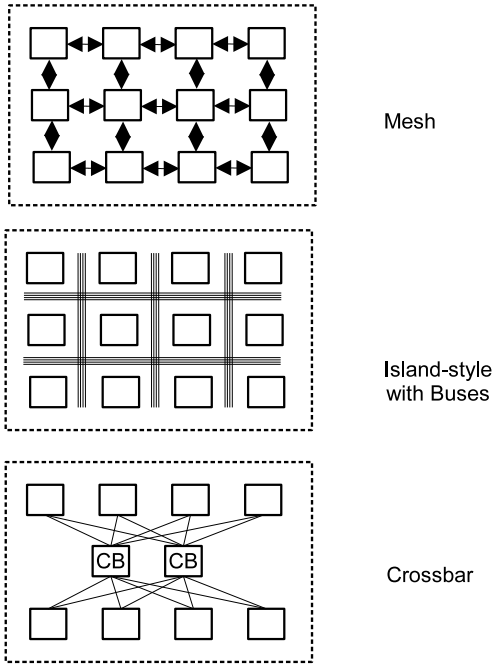

Fig. 2. Three basic types of connectivity

4) Homogeneity/Heterogeneity: Some architectures can use exactly the same logic block for the whole reconfiguration fabric while others can use different types (or even granularity) of logic blocks for the same fabric. For example, the RF shown in Fig. 1 is made of components that are all of the same type. When RF is composed of the same basic logic units it called *homogeneous*. Otherwise it is *heterogeneous* architecture.

5) Coupling: Very often reconfigurable fabric is coupled with a classical, sequential microprocessor. Such systems are named *hybrid processors* because the processing is done by two different types of processors. On the other hand, some architectures use only one type of processor with different modes of operation [5] [4]. Fig. 3 shows 4 possible couplings.

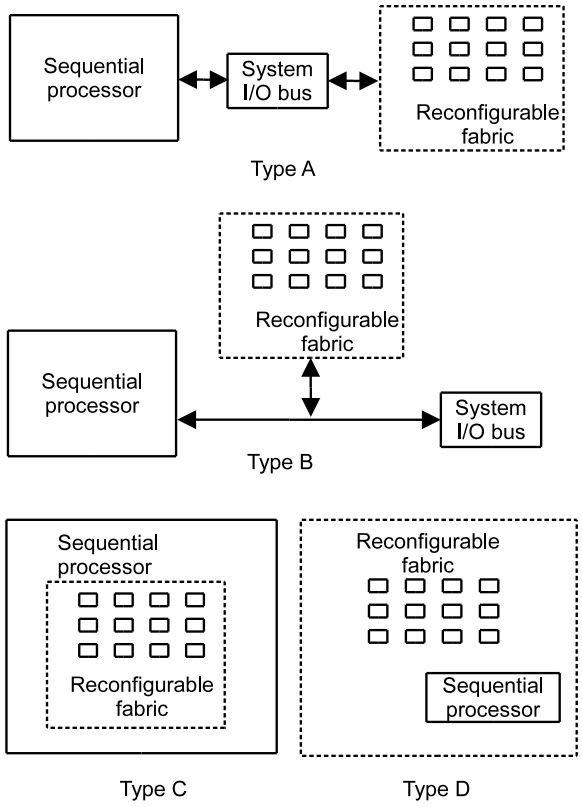

Fig. 3. Four possible couplings between sequential processor and reconfigurable fabric

6) Distribution of local memory: The last comparison criterion can be existence or non-existence of local memory in the basic logic units and in RF as a whole. There are many variants possible and it is not clear whether a limited number of *registers* should be considered as a local memory or not. For example, the architecture shown in Fig. 1 does not use local memory in RF.

B. Architecture classification

Table I shows the features of the several recent architectures: DRP [24] [32]; Matrix [22]; HMP [33] [7]; Tartan [23]; Adres [20] [5] [4]. The Topology column is used for both geometry and interconnectivity.

IV. OWL-BASED PROCESSOR DESCRIPTION

A. Advantages of the OWL language

OWL [13] [16] is a declarative language used for knowledge representation. Primarily it is meant to be used as a description language for defining terms and vocabularies in

Arch.	Granularity	Topology	Coupling	Homog.
DRP	coarse	2D, mesh	Type-D	Yes
MATRIX	coarse	2D, hier.	Type-D	Yes
HMP	coarse	adaptable	adaptable	Yes
ADRES	coarse	2D, hier.	Type-C VLIW+RF	Yes
Tartan	middle	2D, NoC	Type-B	No

TABLE I
OVERVIEW OF ARCHITECTURES

the Semantic Web environment [26] but its usage is widened to many other areas (see [2] for some examples).

The artifact created by the OWL language is called *ontology* and it can represent almost any part (domain) of the overall human knowledge. Most often it is used to specify a hierarchical list of terms e.g. vocabularies. The OWL language is "designed to represent rich and complex knowledge about things, groups of things and relations between things" [16].

The main advantages of the OWL language are that it is a logic-based language with precise, formally defined semantics and that the facts that are not explicitly stated in an ontology can be inferred [2] [16]. The reasoning is done by the program called *reasoner* [31] [27]. The reasoner program can also check the logical consistency of the ontology - the absence of contradictory statements. The OWL language is based on the description logics [2] - a decidable part of the first-order logic.

The main entities used in an OWL-based description of a domain of interest are: individuals, classes and properties.

An individual represents a single object in a domain of interest.

Classes are used to represent a group of individuals that have similar properties. For example, the OWL class named `ReconfigurableProcessor` can be used to represent a class of processors that all use some kind of adaptability.

The OWL properties represent binary relations between individuals or classes.

The following example shows some basic OWL expressions:

```
Ontology: <http://fer.hr/ont/example1.owl>

Class: HybridProcessor
  SubClassOf:
    Processor,
    hasComponent some ReconfigurableFabric,
    hasComponent some SequentialProcessor

Class: ReconfigurableFabric
    SubClassOf:
     hasComponent some BasicLogicBlock

Class: Processor
Class: ProcessingElement
Class: BasicLogicBlock

ObjectProperty: hasComponent

Individual: SmartProcessorX
    Types: HybridProcessor
```

Example 1: OWL ontology can contain: individuals, classes and properties.

The main statement (OWL terminology defines "statement" as "axiom") is one that says that "Hybrid processors are the type of processors that have some ReconfigurableFabric and some SequentialProcessor". Another axiom claims that "SmartProcessorX is an individual, the instance of the HybridProcessor class".

The OWL syntax used in the above example is called Manchester syntax. Other syntaxes are possible as well (RDF/XML, OWL/XML, functional syntax and Turtle syntax) [13]. Once the ontology is completed it can be saved as an XML file. Programs can access the data in the ontology through application interface (API). The OWL API [3] (http://owlapi.sourceforge.net/) is a standard Java OWL library for the ontology data manipulation.

It is important to note that, although the above names ("Processor" or "hasComponent") have certain meaning in English language, their semantics in the ontology are defined only by the axioms present in that ontology. Neither OWL language by itself, neither ontologies nor reasoning programs understand the usual (English) language semantics.

Each ontology has unique name by which it can be referred to (defined by the first line in the above example).

While some classes (such as `Processor` in Example 1) are not constructed in the ontology, but merely mentioned to be a class, others (such as `HybridProcessor`) can be constructed by existing ones. The expressions that construct complex classes from the primitive ones use classes, properties and various logical operators.

In the above example the logical operators used are AND operator and "some" operator. The AND operator is written as a comma character while the "some" operator is, in fact, existential operator: $\exists$.

For example, in the following OWL expression:

```
Class: ReconfigurableFabric
    SubClassOf:
     hasComponent some BasicLogicBlock
```

the line `hasComponent some BasicLogicBlock` implicitly defines new no-name class. This no-name class defines a set of individuals that all have, as a component, individual that is an instance of the `BasicLogicBlock` class. The `ReconfigurableFabric` class is defined as a subclass of this no-name class.

OWL properties, like OWL classes, can form a hierarchy in a sense of "is-a" relation. For example, properties such as `hasComponent` and `hasMember` can be defined as subclasses of the more general `hasPart` property.

There are two types of properties in OWL. The first, called `ObjectProperty`, defines relation between two OWL classes or between two OWL individuals. The second defines relation between an individual or class and some data value. For example, in OWL we can state that "AdultPerson hasAge moreThen 18". In this case `hasAge` property relates to some data (18) and not to some other individual or class.

The latest version of the OWL language is OWL 2 (see [13] for OWL documents overview). It has 2 main dialects (OWL 2 DL and OWL 2 Full) and 3 "profiles". These variations of the OWL language differ in complexity. More complex dialects are more powerful and can be used to describe more demanding domains but the power comes at the cost of more complicated reasoning. Ultimately the

most powerful OWL 2 Full is undecidable. The reasoning for the decidable dialects of the OWL 2 language is sound and complete.

B. OWL-based processor architecture description

The ontology used in this work is constructed by the Protègè editor (http://protege.stanford.edu) from Stanford University [18]. Protègè is a widely accepted knowledge editor that can be used to construct complex ontologies. It can use independent reasoners such as Pellet [27] and FACT++ [31] whose functions can be called from the inside of the editor. The main function of the reasoner program is to classify all the facts in ontology according to the is-a relationship [2].

If the ontology is saved as an XML file, the file can be viewed as a *XML configuration file* for various software tools. Using XML for defining configuration is a well established and common practice in many areas.

The following OWL ontology will extend the ideas sketched in Example 1 from previous section. Due to space restrictions it will be *simplified and incomplete* but will illustrate the main ideas. (It is assumed that the `HybridProcessor` class is defined earlier and that classes `MainMemory`, `DMA` and `ControlLogic` are the primitive ones). The complete ontology will be divided into separate parts for easier explanation.

The first part defines computing system that has several basic components:

```
Class: HybridSystem
  SubClassOf:
    hasComponent some HybridProcessor,
    hasComponent some MainMemory,
    hasComponent some DMA,
    hasComponent some ControlLogic

Class: MainMemory
Class: DMA
Class: ControlLogic

ObjectProperty: hasComponent
  InverseOf: isComponentOf
  Characteristics: Transitive

ObjectProperty: isComponentOf
  InverseOf: hasComponent
  Characteristics: Transitive
```

The `hasComponent` object property can be viewed as a special type of the more general `hasPart` property. (That fact is not shown in the ontology).

The `hasComponent` and `isComponentOf` properties are defined as inverse. This will enable the reasoner to infer that if `A isComponentOf B` than `B hasComponent A`. Also, these properties are defined as `Transitive` with common meaning that if `A isComponentOf B` and `B isComponentOf C`, it implies that `A isComponentOf C`.

The second part of the ontology defines terms in the Geometry/Connectivity area:

```
Class: Topology

Class: Topology1D
  SubClassOf: Topology

Class: Topology2D
  SubClassOf: Topology

Class: Connectivity

Class: NeighbourOnly
  SubClassOf: Connectivity

Class: PESide
  EquivalentTo: East or West
    or North or South
```

Most of the above description is self-explanatory. Only the `PESide` class needs explanation. It is a side of some processing element and can have one of the possible four directions. The PESide class is defined (`EquivalentTo`) to be one of the four possibilities (`East, West,...`). Note that other classes are not defined. The *definition* of some class is composed of necessary *and* sufficient conditions, while normal, non-defined classes have a list of necessary conditions only.

The third part expands the terms from Example 1 for the `ReconfigurableFabric` class:

```
Class: ReconfigurableFabric
  SubClassOf:
    hasComponent some BasicLogicBlock

Class: Coarse-GrainedFabric
  SubClassOf: ReconfigurableFabric,
    hasComponent all
     (hasGranularity Coarse))
```

Every component in `Coarse-GrainedFabric` has coarse granularity (operator `all`).

The processing elements (PE) used in the DRP architecture are defined as follows:

```
Class: DRPProcessingElement
  SubClassOf:
    BasicLogicBlock,
    hasRole some (ConnectionElement or
      FunctionElement),
    hasComponent exactly 4 PESide,
    hasComponent PEOperationList,
    hasComponent PEInput,
    hasComponent PEOutput,
```

The `PE` is defined as a type of `BasicLogicBlock` that can work as a `ConnectionElement` or a `FunctionElement`. If working in a connection mode, PE will route its inputs to outputs only (without processing). If it works in a function mode, it will compute some function and send result to the outputs. The available operations of the PE are enumerated in the `PEOperationList` (not shown).

And finally, the DRP architecture, shown in Fig. 1. is defined as a hybrid processor with coarse-grained granularity, 2D topology and neighbor-only connectivity.

```
Class: DRP
  SubClassOf:
    HybridProcessor,
    hasFabric Coarse-GrainedFabric,
    hasComponent some DRPProcessingElement,
    hasTopology some Topology2D,
    hasConnectivity some NeighbourOnly
```

The main advantages of the OWL usage for processor architecture description can be summarized in the four main points:

1) OWL is a well known language suitable for processor architecture specification - there is no need to invent something new.

2) The OWL ontology of the processor architecture can be stored in an XML file - common practice in SW engineering and configuration descriptions.
3) For complex specifications where some validation of facts is necessary, there is a formal method for consistency checking - we can be assured that there are no contradictions present.
4) The reasoner program can be used to infer facts about architecture that are not explicitly stated.

V. Conclusion and future work

The paper deals with two problems: (i) how to classify a great number of different reconfigurable processor architectures and (ii) how to precisely describe processor architecture.

The main contribution of the paper is the OWL-based description of processor architectures. This approach has already been successfully tested as a part of the compilation tool project. Consistency checking of complex specifications can be error prone but now it will be done by the reasoner program. Our work in this area (not described in this paper) has proved that such descriptions, once defined, are excellent building blocks in the process of constructing hardware and software for the new processor architecture.

Future work will include refining of the OWL description and using it as an input for the compiler for the DRP processor.

A novel solution for realisation of data transfer in borehole measurement systems

brxnet@yahoo.com

In the borehole measurements it is generally beneficial to be able to conduct a larger number of measurements at the same time, which results in large amounts of data that has to be send from measurements probes to surface. Most borehole systems as transmission line use monoconductor electromechanical cable with small cut-off frequency. In this paper a novel method of data transfer over monoconductor electromechanical cable is presented. This method uses HDB3 (high density bipolar of order 3) line encoding and system for reconstructing of the received signal. It achieves higher bit rates than usual methods used in borehole systems. Advantages of this method are discussed and system based on this method is presented in this paper. System is realized and measurement results are presented.

I. INTRODUCTION

In the process of development wells, to determine the geological formation and physical properties of soil it is necessary to perform measurements of various geophysical quantities. These measurements are commonly called geophysical measurement (GPM) [1].

Measurements are performed using probes which are lowered to the bottom of the borehole and then lifted up at constant speed, so that the measurement and sending of the measured parameters to the surface unit are carried out simultaneously.

The main components of GPM system are (Fig.1):

1 - Surface unit for analysis and monitoring of measured results

2 - Cable for lowering the probe through the tested well and communication link between the measuring instruments and surface units.

3 - Measuring probe.

In the well logging business it is generally beneficial to be able to combine as many types of logging probes as possible into one continuous instrument package, known as a "tool string". The intention is to reduce the number of times logging equipment has to be descended into the borehole, which can save a considerable amount of operating time.

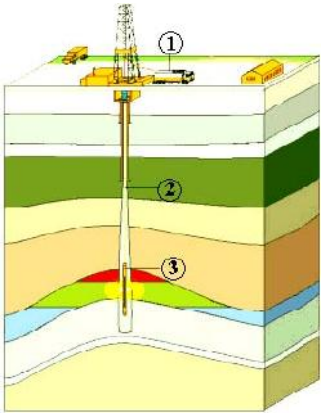

Figure 1. Borehole measurement system

Combining a larger number of measurements requires large amounts of data to be sent to the recording system on the surface. It can cause the required data transmission rates to exceed the signal carrying capacity of the well logging cable. This problem is particularly acute when the imaging probes are included in the probe string, which can lead to considerable increase in the amount of data to be transmitted to the surface. One of the solution is to use multi-wire cable, method used in paper [2] was able to achieve 100 kbps, but with 4-wire cable length of 3000 meters. Discrete multi-tone modulation is also used [3], which can achieve higher data rates, but again cable with multiple wires (7-wire) was used. Since monoconductor cables are in general use in logging industry, changing logging cables would lead to significant investment increase, so novel solution for higher data speed is developed and presented in this paper.

In section II, properties and data transfer problem of wireline cable is explained. In section III, HDB3 code (High Density Bipolar) code is described. In section IV, hardware realization of data transfer system is presented. Measurement results are presented in Section V, followed by conclusion in Section VI.

II. WIRELINE CABLE DATA TRANSFER

Because of high pressures (up to 100MPa) and temperatures (up to 200C) [4] in deep boreholes, robust electromechanical "wireline" cables are regularly used at geophysical measuring as conventional medium for data transmission. They are composed of central copper

conductor, strong conductive steel wire protective armor, and dielectric placed in between. This specific construction (steel armor ,dielectric material, cable geometry…) results in relative high series resistance per unit length (around 10-50 Ohm/km), and high capacitance per unit length (around 100-1000 pF/m), and since usual length for oil boreholes logging cables is around 5000-7000 meters, band-pass frequency of this cables is very low, in order of kHz. Any cable can be regarded as transmission line, for condition:

$$l > \frac{\lambda}{4} = \frac{1}{4}\frac{c}{f} \qquad (1)$$

Where l is length of the cable, λ- signal wavelength, c-speed of light, and f frequency of the signal.

In case of usual borehole cable, this condition is true for frequencies above ~10 kHz. Simplified model for transmission line is series of low pass filters, so all signals with frequencies above band-pass are highly attenuated.

Graphic representation of the gain-frequency response (also referred as the "transfer function") of a typical well logging cable is given in Fig. 2. It can be seen that cutoff frequency is around 2 kHz, and that attenuation slope is increased with frequency.

Frequency response was measured on 6000 m cable, blue part of the line presents measured points of frequency response, after 70 kHz output signal became too small to be measured, and so red line presents extrapolation part of response.

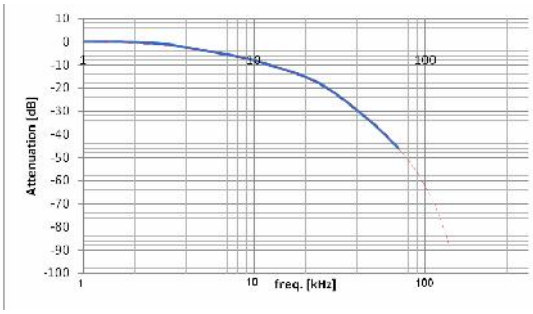

Figure 2. Well logging cable frequency response

Besides data transfer, wireline cable is used as DC power supply to measuring probes, which requires specific input and output stages in communication system, since separation of communication data and DC component must be performed.

In first borehole probes "impulse" communication systems were used. These systems were based on sending data from probe by imprinting positive or negative impulses in DC signal, and counting impulse on receiver. Numbers of impulses in defined time interval (usually one second) were directly proportional to amplitude of signals from probe. These systems were very robust, simple and insensitive to noises, but transfer speed was very low, below 1 kbps [4].

In order to increase the effective signal data carrying capability of the logging cable, various types of encoding methods are used. One of the most common and widely used is the Manchester coding, described in [5] and [6] . The main disadvantage of Manchester code is that for each bit of data the carrying signal has to be swapped between two logical states. This means the effective bit rate is the same as the carrier signal frequency. As the frequency increases the greater is the attenuation the cable introduces.

For a desired bit rate of e.g. 100 kbps with Manchester coding needed frequency would be 100 kHz and the attenuation would reach -60 dB, which is far beyond proper regeneration. In comparison to Manchester, for the same carrier frequency, HDB3 code provides twice the bit rate. So for 100 kbps, signal of maximum 50 kHz have to be transmitted over the line, which is considerably easier to reconstruct and decode.

III. HDB3 ENCODING

The HDB3 is a bipolar code based on AMI (Alternate Mark Inversion) coding for transmission over the line. AMI is a balanced code that encodes consecutive 'ones' into either positive or negative pulses in an alternating pattern; 'zeros' generate no pulses. In addition to AMI which provides a change of polarity for every 'one' transmitted, HDB3 insures that no more than three consecutive 'zeros' are transmitted on the line by inserting BPV (Bipolar Polarity Violation) codes whenever there is a run of four or more 'zeros'. The use of BPV's in the signal give it extra edges which makes synchronization possible and data retrieval more accurate.

An additional function of HDB3 encoding is to eliminate DC offset on the transmission line. BPV's of the same polarity would create a DC offset. Therefore every BPV needs to be of the opposite polarity to the previous BPV. To realize this, an additional 'one' needs to be inserted if the previous BPV polarity is the same as the BPV polarity to be inserted. This additional 'one' is inserted at the position of the first 'zero' in the 'four zero' sequence.

There are four rules for HDB3 coding:

I. More than three consecutive 'zeros' are not allowed to be present in the waveform. For the fourth 'zero' a violation bit is introduced.

II. Violation bit has to be of the same polarity as the previous mark.

III. Two consecutive violation bits have to be of opposite polarity.

IV. If the number of marks between two consecutive violation bits is even, the format should be B00V, where B is a stuffing bit and of opposite polarity to the previous mark. If the number of marks is an odd number the format should be 000V.

These rules are applied on the code as it is being built from the original string. Some examples are given in Fig. 3 and Fig. 4.

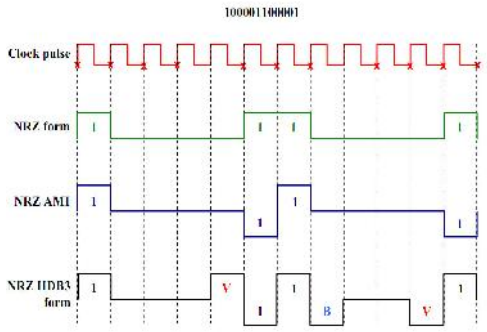

Figure 3. HDB3 coding example

Assuming that the previous bit was a positive mark, a series of zeros will be coded according to HDB3 rules as follows:

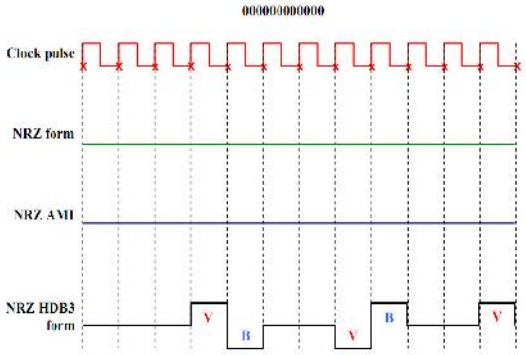

Figure 4. HDB3 coding example

IV. HARDWARE REALIZATION

Using an improved line driver the HDB3 signal, generated by a MCU in the downhole telemetry section, is transmitted to the surface over a monoconductor cable. Basic schematic of typical line driver, described in detail in [4], is shown on Fig 5. By pulling capacitor C to ground through transistor, negative impulses are imprinted in line signal. Similar circuit is used for generating positive impulses.

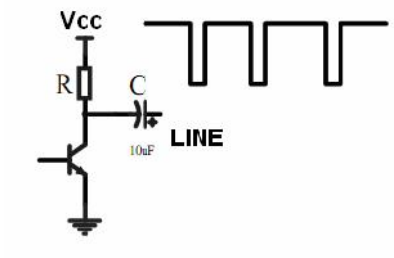

Figure 5. Typical line driver

Driver for HDB3 signal needs to be able to generate three different impulses: positive, negative and "zero". An example of such a signal is given in Fig. 6.

Figure 6. The transmitted signal

A. HDB3 receiving section

Impulses that arrive through the cable are significantly distorted, because of its limited signal transmission capacity. An example of a signal on the input of the receiving section is shown in Fig. 7.

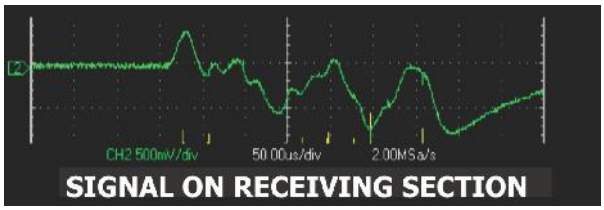

Figure 7. Signal on receiving section

In order to be reconstructed, the received signal has to pass through a series of attenuators and filters. A block diagram of the receiving section is shown in Fig. 8.

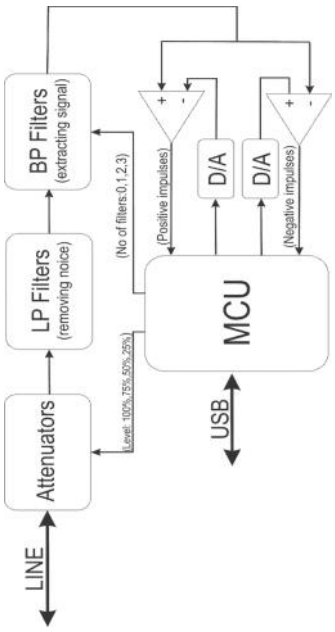

Figure 8. Block diagram of the receiving section

At first signal passes through a variable attenuation section and 4th order low pass (LP) filter section. These LP filters remove high frequencies environmental noise. The filtered signal is further transferred to a band-pass (BP) filter section. This section consists of maximum of 3 equivalent band pass filters in series. BP filters restores the original signal so it can be reconstructed on positive and negative impulses by comparators.

The amplitude characteristic of one of this filter is shown in Fig. 9. It can be seen that in area of interest, in this case from 1 kHz to 100 kHz, curve of amplitude response is approximately inverse of curve on Fig. 2. Frequencies below 100 Hz are heavily attenuated, to eliminate DC component in line signal.

B. Calibration procedure

Signals after each filter level are shown on Fig. 10. It can be seen that each filter section inverts the signal. In an ideal case the frequency response of BP filter section should be exactly the inverse frequency response of currently used well logging cable. Since same data transfer unit is usually used for several years on same well logging cable, calibration procedure is done only once for same logging cable. The desired filter level depends on the length of the cable used, and its frequency response. Length and cutoff frequency of logging cable is used as a starting position for approximate selection of number of used BP filter. Selection is made by USB communication through MCU by controlling a set of analog switches, which changes the number of used BF filters. It is possible to select from no BP filter (for very short cables, where there is no significant distortion to signal) to three BP filter in series, with every additional BP filter increases the slope on amplitude response in area of interest. Watching the output signals of BP filters on oscilloscope as on Fig. 10 and changing its number, it is possible to adjust total filter response so that on output of filter section received signal is regenerated enough to be properly reconstructed. This procedure was successful in all cables we tested, but there is possibility that this wont be enough on some cables, in which case manually changing of BP filter characteristic (by changing its components, resistors and capacitors) will be needed.

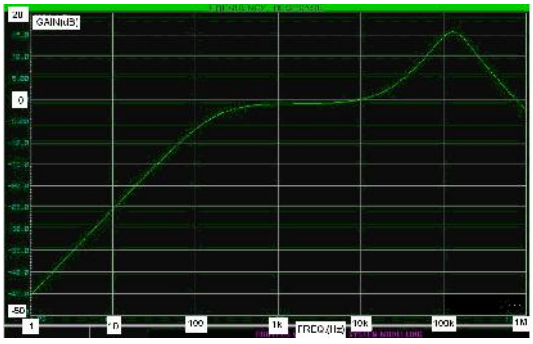

Figure 9. Amplitude characteristics of one BP filter

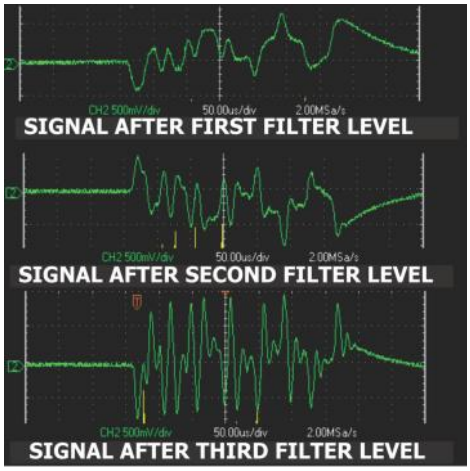

Figure 10. Signal after each filter level

After the band pass filter section the signal is passed to two comparators which transform bipolar signal into positive and negative unipolar impulses. The MCU automatically adjusts the positive and negative comparator levels during the calibration process, depending of the amplitude level of received signal. If signal amplitude is too high, it can be decreased with attenuators, realized with analog switches controlled by MCU. Outputs of the comparators are shown on Fig 11. It can be seen that positive and negative impulses correspond to negative and positive impulses from the probe, so original signal can be reconstructed. These impulses are further transferred to a pair of input pins of a MCU, to be decoded.

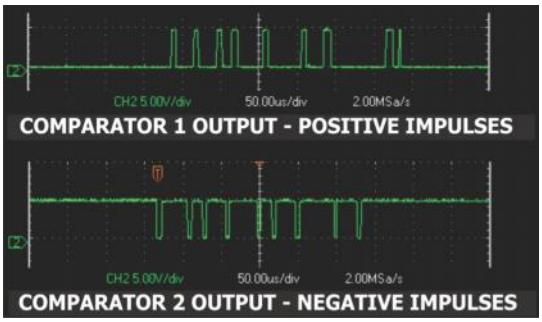

Figure 11. Comparator outputs

The MCU communicates with PC acquisition system over USB protocol. By using PC software it's possible to setup communication speed, and also set calibration values for particular cable manually and automatically.

V. MEASUREMENT RESULT

System is realized and tested in laboratory conditions and on borehole. Also, wireline cable and data transfer system were simulated using Proteus simulation software. Simulation was used to test if the system can be used for worst case of wireline cables, with maximum length and resistivity and capacitance of the cable, since this type of cable wasn't available for testing. It was determined that speed up to 100 kbps can be achieved in this type of cable.

For testing in laboratory conditions, cable of 5000 meters was used and maximum speed of 130 kbps was achieved. Also, temperature testing of system up to 175 C was conducted, no change of maximum transfer speed was noticed.

VI. CONCLUSION

In this paper realization of data transfer system for borehole measurement was presented. With this novel data transfer system it's possible to send a large amount of data through a monoconductor cable, so more logging equipment can be used in same time.

It was noticed that depending of the cable characteristic, band pass filter parameters must be adjusted to achieve required transfer speed, in this system this was conducted manually for specific cable, further improvement of this system could be digitalization of analog filters by using FPGA or DSP processor, which would improve the parameter flexibility of filters used in receiver . Higher transfer speeds could also be achieved with this improvement, since better filters could be realized.

***Abstract*—The simplest multiplierless decimation filter is the cascaded-integrator-comb (CIC) filter. However, the magnitude response of this filter has a high passband droop, which is not tolerable in many applications. The droop can be reduced by the filter called CIC compensator. In this paper, we present a method for the design of finite-impulse-response CIC compensators whose coefficients are expressed as the sums of powers of two (SPT). The method is based on the minimax error criterion. To obtain the SPT coefficients, we use a global optimization technique which is based on the interval analysis. The proposed compensators are multiplierless and result in wide compensation bands. Therefore, they are suitable for application in software radio receivers operating with low decimation factors.**

I. INTRODUCTION

Digital down converters (DDC) usually employ the cascaded-integrator-comb (CIC) filter [1] in the first stage. It is the consequence of its efficient multiplierless structure. However, the magnitude response of the CIC filter has a significant passband droop, which is not tolerable in many applications. The droop can be reduced by modifying the original CIC structure or by connecting an additional filter called CIC compensator in the cascade with the CIC decimator. The former approach is based on the sharpening technique. The sharpening of CIC filters is described in [2]–[4]. In the latter approach, the CIC compensator is realized as a linear-phase finite-impulse-response (FIR) filter, which yields the constant magnitude behavior of the overall cascade. Recently, many methods for the design of CIC compensators have been developed [5]–[11]. In [12], compensation is combined with sharpening technique.

In a software radio receiver which uses a DDC with high decimation factor, for example in [5] and [13], the compensator operates at a low sampling rate. Therefore, it can be realized as a standalone FIR filter which is implemented using the multiplier-accumulator block, or it can be incorporated into the channel filter thus avoiding extra multipliers. On the other hand, in a receiver using low decimation factor, the compensator with multiplierless structure is preferable. Such a compensator often has discrete coefficients which are expressed as the sum of powers of two (SPT), [5], [7]–[9], [11]. In the papers referred to, the multiplierless compensators with three [5], [7]–[9] and five [11] coefficients have been proposed. They result in compensation over a narrow [5], [7], [11] or a wide band [7]–[9], [11]. Various criteria have been used in their design, such as the least squares [8], minimax [9], and maximally flat [11]. In addition, the requirement for a low complexity has been considered in [5] and [7].

In this paper, we present a method for the design of CIC compensators with SPT coefficients. The design is based on the minimax error criterion. It employs the interval analysis to obtain the optimum coefficients. The optimization based on the interval analysis results in global solution. Recently, it has been successfully used in the design of low-order FIR filters with SPT coefficients [14]. Here, we modify the method in [14] for the design of CIC compensators.

II. CIC COMPENSATOR WITH SPT COEFFICIENTS BASED ON MINIMAX ERROR CRITERION

A. CIC Compensator

The transfer function of the CIC filter of order N is given by [1]

$$H_{CIC}(z)=\left(\frac{1}{R}\frac{1-z^{-R}}{1-z^{-1}}\right)^{N} \tag{1}$$

where R denotes the decimation factor. The corresponding amplitude response is

$$H_{CIC}(\omega)=\left[\frac{1}{R}\frac{\sin\left(\frac{\omega R}{2}\right)}{\sin\left(\frac{\omega}{2}\right)}\right]^{N} \tag{2}$$

The CIC compensator is connected to the output of the CIC decimator. Therefore, the amplitude response of the ideal compensator is obtained as the inverse amplitude response of the decimation filter relative to the low sampling rate, as in

$$H_{C}(\omega)=\frac{1}{H_{CIC}\left(\frac{\omega}{R}\right)} \tag{3}$$

This paper was supported by the Ministry of Science, Education and Sports of the Republic of Croatia under grant no. 036-0362214-2217, and the ACROSS project funded by the Seventh Framework Programme of the European Union under grant no. 285939 FP7-REGPOT-2011-1.

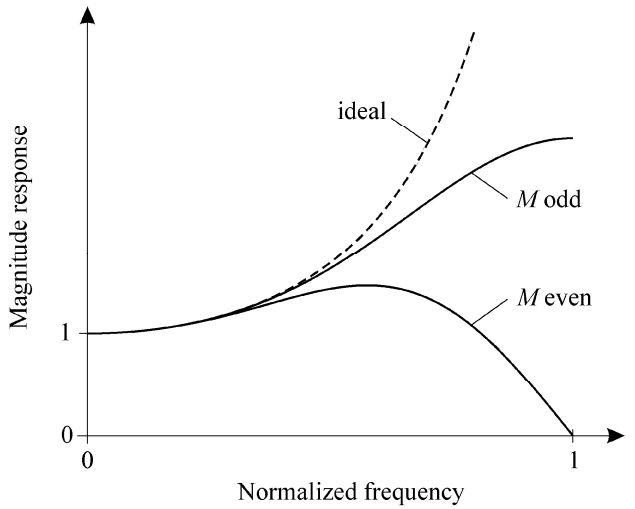

Figure 1. Magnitude responses of ideal and FIR CIC compensator with even and odd number of coefficients, *M*.

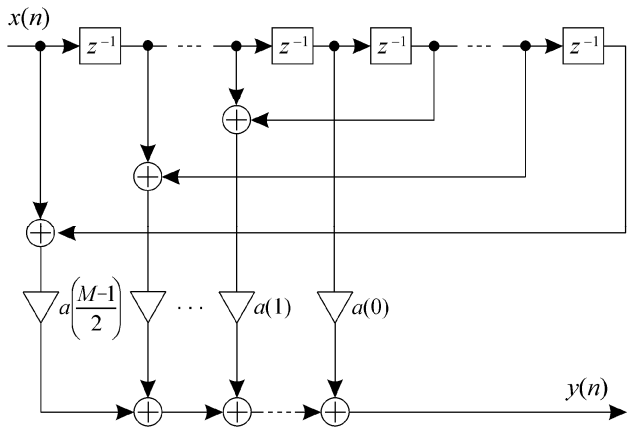

Figure 2. Folded delay-line structure of CIC compensator with odd number of coefficients, *M*.

By substituting (2) into (3), the ideal compensator's response is obtained as

$$H_C(\omega)=\left[R\frac{\sin\left(\frac{\omega}{2R}\right)}{\sin\left(\frac{\omega}{2}\right)}\right]^N \tag{4}$$

FIR compensators can be realized with odd or even number of coefficients. Both cases are discussed in literature. However, the compensators with odd number of coefficients approximate the ideal response in a wider band than do the compensators with even number of coefficients, as shown in [10]. It is a consequence of the transfer function zero placed at $z=-1$, which appears in the transfer functions of the compensators with even number of coefficients. Such a zero deteriorates the magnitude response in the vicinity of $|\omega|=\pi$, as illustrated in Figure 1. Therefore, in the following text, only the compensators with odd number of coefficients are considered.

B. Minimax Approximation With SPT Coefficients

Let us consider a system which consists of a CIC filter cascaded with a linear-phase FIR compensator. The magnitude response of such a system should approximate a constant within a given band, known as the care band. Our objective is to find the optimum SPT coefficients of the compensator which results in the minimax approximation. Such a design is described by the optimization problem

$$\mathbf{a}_{opt}=\arg\min_{\mathbf{a}}\left[\varepsilon(\mathbf{a})\right] \tag{5}$$

$$\text{subject to : } \mathbf{a} \text{ is SPT representable} \tag{6}$$

where **a** is the vector of compensator's coefficients. The objective function, ε, has the form

$$\varepsilon(\mathbf{a})=\max_{|\omega|\le\omega_c}\left|1-H_{CIC}\left(\frac{\omega}{R}\right)H(\omega,\mathbf{a})\right| \tag{7}$$

where $H(\omega,\mathbf{a})$ is compensator's amplitude response, and ω_c is the upper bound of the care band. Linear-phase FIR system has symmetric impulse response. Therefore, for a compensator with odd number of coefficients, *M*, vector **a** contains only $(M+1)/2$ right-hand side samples, as in

$$a(m)=h\left(m+\frac{M-1}{2}\right)\quad;\quad m=0,1,\ldots,\frac{M-1}{2} \tag{8}$$

where **h** is compensator's impulse response. Using (8), the amplitude response of the compensator is given by

$$H(\omega,\mathbf{a})=a(0)+2\sum_{m=1}^{(M-1)/2}a(m)\cos(m\omega) \tag{9}$$

For a given wordlength *K*, the SPT representation of compensator's coefficients, $a(m)$, is given by

$$a(m)=\sum_{k=1}^{K}b(m,k)2^{-k}\quad;\quad m=1,\ldots,\frac{M-1}{2} \tag{10}$$

where $b(m,k)\in\{-1,0,1\}$. Each $b(m,k)\neq 0$ is called a term. In implementation, it is represented by one adder. Therefore, the number of terms per compensator or the number of terms per coefficient is limited to a prescribed value, *P*. For simplicity, here we use the latter approach.

Since the desired response in (4) occupies a wide band, the impulse response of an FIR compensator is expected with the energy which is highly concentrated in the coefficient $a(0)$. Therefore it is reasonable to assign one term more to it than to the other coefficients. Here, we assume it contains the term 1 belonging to 2^0. Therefore, we deal with $a(0)$ expressed as

$$a(0)=1+\sum_{k=1}^{K}b(0,k)2^{-k} \tag{11}$$

Since the CIC compensator has a symmetric impulse response, we realize it using the folded delay-line structure, which is shown in Figure 2. The total number of adders employed in this structure is given by

$$A=M+B-1 \tag{12}$$

where *B* is the total number of adders required for the realization of multiplications by $a(0)$, $a(1)$, ..., and $a((M-1)/2)$. Since coefficient $a(0)$ has up to $P+1$ terms,

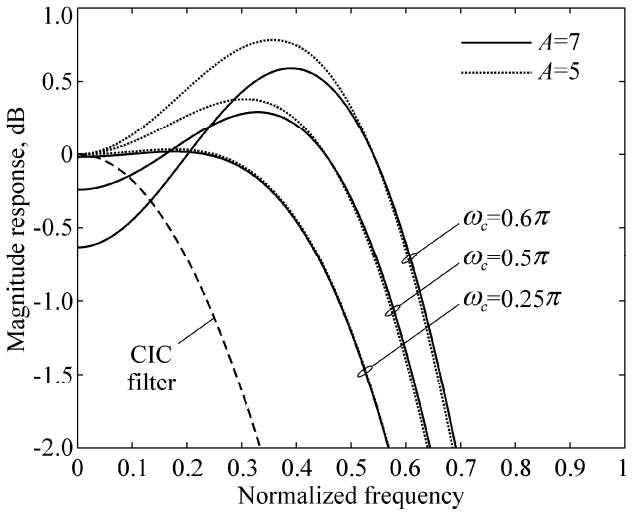

Figure 3. Magnitude responses at low sampling rate of CIC filter with N=5 and R=14 compensated with minimax compensator having M=3 SPT coefficients and total number of adders, A. Minimax compensation is made within care band $|\omega| \le \omega_c$.

whereas other coefficients have up to P terms each, B satisfies the inequality

$$B \le \frac{M+1}{2}(P-1)+1 \tag{13}$$

Substituting (13) into (12), the number of adders required for the realization is given by

$$A \le \frac{(M+1)(P+1)}{2} - 1 \tag{14}$$

In practice, if wordlength K is high enough the upper bound of A is achieved.

C. Design of Compensator Based on Interval Analysis

In this paper, we use the optimization based on the interval analysis to obtain the optimum compensator. Such an optimization is attractive since it results in global solution. A comprehensive overview of the optimization via the interval analysis reader can find in [15] and [16]. Such an optimization is used in the design of linear-phase FIR filters with SPT coefficients, which approximate a given magnitude in the minimax sense [14]. In the paper referred to, the design is described by the optimization problem

$$\mathbf{x}_{opt} = \arg\min_{\mathbf{x}} \left[y(\mathbf{x}) \right] \tag{15}$$

$$\text{subject to}: \mathbf{x} = \left[x(m) \right] ;$$

$$x(m) = \sum_{k=1}^{K} b(m,k) 2^{-k}; \; m = 0,1,\ldots,\left\lfloor \frac{M-1}{2} \right\rfloor \tag{16}$$

where M is the number of filter's coefficients. The objective function y is given by

$$y(\mathbf{x}) = \max_{\omega \in \Omega} \left[W(\omega) \left| H_a(\omega, \mathbf{x}) - H_d(\omega) \right| \right] \tag{17}$$

where $H_a(\omega,\mathbf{x})$ is filter's amplitude response, $H_d(\omega)$ is a desired magnitude response which is defined within some band of interest Ω, and $W(\omega)$ is a positive weighting function.

The method in [14] can be easily modified to cover the design of the compensator. To deal with vector $\mathbf{x}$ we have to modify the objective function in (7), or rather, the compensator magnitude response in (9). By substituting (10) and (11) into (9) and then by applying (16) into the response obtained, we arrive at

$$H(\omega, \mathbf{x}) = 1 + x(0) + 2 \sum_{m=1}^{(M-1)/2} x(m) \cos(m\omega) \tag{18}$$

Finally, by substituting (18) into (7), the modification of the objective function is obtained as

$$\varepsilon(\mathbf{x}) = \max_{|\omega| \le \omega_c} \left| 1 - H_{CIC}\left(\frac{\omega}{R}\right) H(\omega, \mathbf{x}) \right| \tag{19}$$

It should be noted that solving the problem in (15)–(17) is based on the interval extension of the objective function. In the design of the compensator, which is described by (15), (16), (18), and (19), the interval extension of the error function in (19) can be easily obtained by using the extensions of elementary operations, as described in [14].

III. Features of Proposed CIC Compensators

To illustrate the features of the proposed compensation, three examples are described. The first example presents the design of compensators whose impulse responses have only three coefficients. The second example describes the design of wideband compensators. Finally, the design of low-complexity compensators are considered in the third example.

The results obtained are provided in Table I and Table II. The coefficients are tabulated for various orders of CIC filter, care bands, and complexities, assuming R=1024 and K=18. It is well known, for $R \ge 10$ the change of R does not influence the shape of the passband response of the CIC filter significantly [1]. In that sense, the coefficients given in the tables can be used for the compensation of CIC filters with $R \ge 10$.

A. Compensators With Three Coefficients

In many applications, the compensators with only three coefficients are usually sufficient. To illustrate the features of the proposed design, the compensation of the CIC filter with N=5 and R=14 is described. The compensation is considered over the bands with the upper bounds $\omega_c = 0.25\pi$, 0.5π, and 0.6π. If $\omega_c \ge 0.5\pi$ the compensation is considered as wideband, otherwise it is narrowband. Two compensators with different complexity are designed. Their coefficients are obtained for wordlength K=9 and for the number of terms P=2 and P=3, what results in the structures with A=5 and A=7 adders. Figure 3 shows the compensated magnitude responses together with the response of the uncompensated filter. As expected, increasing the passband causes decreasing the quality of compensation. However, the compensators whose structures employ up to seven adders improve the magnitude significantly. For example, if the passband is $|\omega| \le 0.5\pi$, the CIC filter introduces the droop of 4.5dB. The droop of the compensated filter as low as 0.3dB is

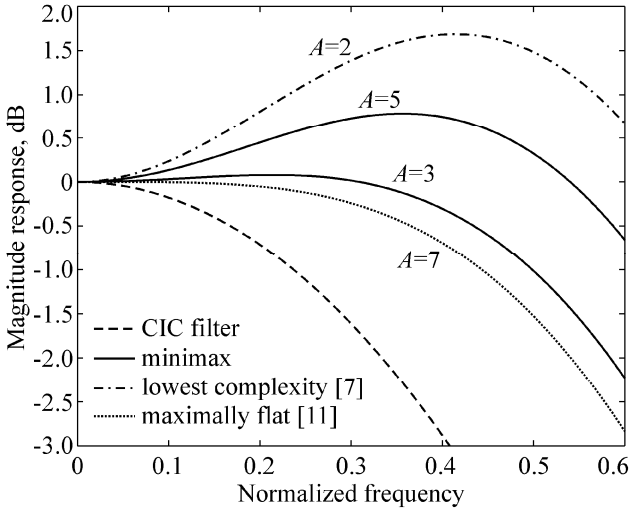

Figure 4. Magnitude responses at low sampling rate of CIC filter with N=5 and R=14 compensated with minimax compensator and compensators proposed in [7] and [11]. All compensators have M=3 SPT coefficients and A adders. Care band is $|\omega|\leq 0.6\pi$.

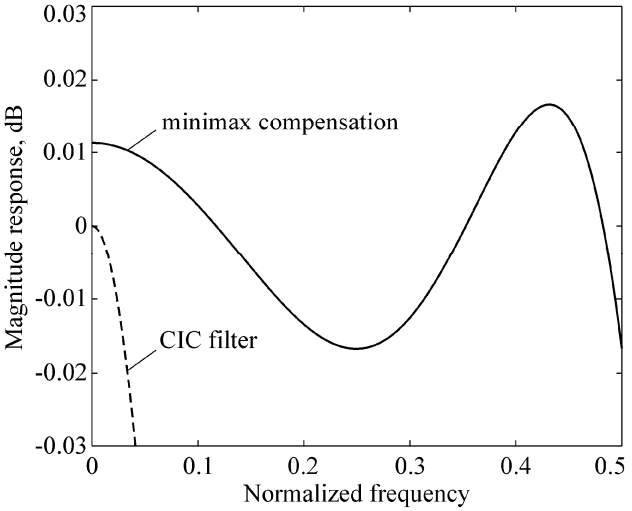

Figure 6. Magnitude responses at low sampling rate of CIC filter with N=5 and R=1024 compensated with minimax compensator having M=7 SPT coefficients and 19 adders. Care band is $|\omega|\leq 0.5\pi$.

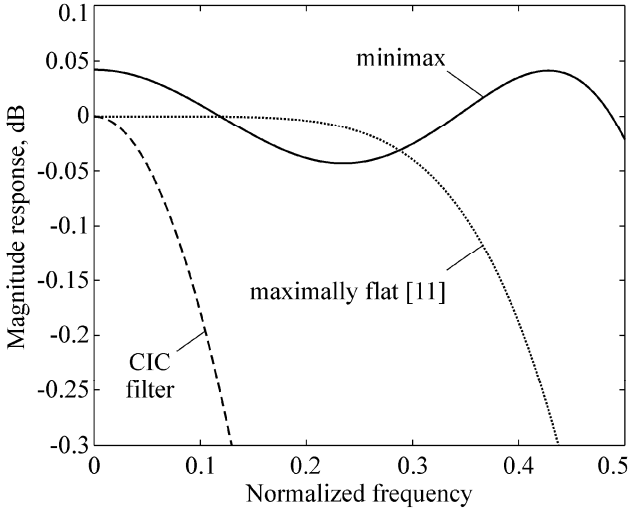

Figure 5. Magnitude responses at low sampling rate of CIC filter with N=5 and R=32 compensated with minimax and maximally-flat [11] compensator having M=5 SPT coefficients. Minimax compensation is made within care band $|\omega|\leq 0.5\pi$.

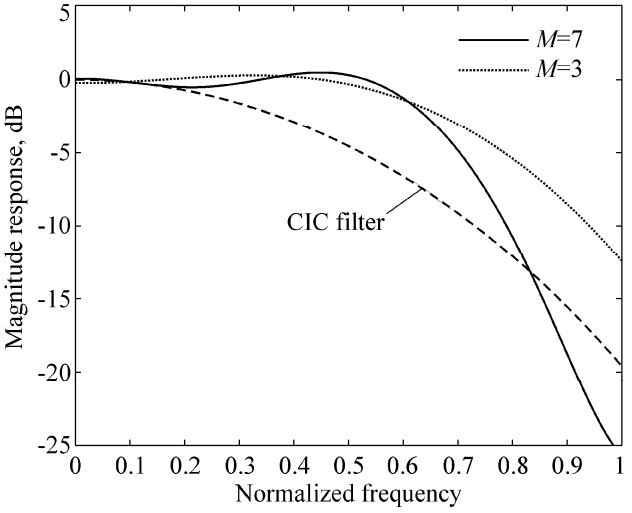

Figure 7. Magnitude responses at low sampling rate of CIC filter with N=5 and R=32 compensated with minimax compensator having M coefficients and seven adders. Care band is $|\omega|\leq 0.5\pi$.

achieved for the compensator with seven adders. However, further increasing of the number of adders improves the compensation negligibly.

Let us now compare our compensator with the maximally flat compensator [11] and the compensator having the lowest possible complexity [7]. The compensation of the CIC filter with N=5 and R=14 over the band $|\omega|\leq 0.6\pi$ is considered. The lowest-complexity compensator employs two, whereas the maximally flat compensator employs seven adders. The design of the minimax compensators with K=4 and with P=1 and P=2 results in the structures with A=3 and A=5 adders. Figure 4 shows the magnitude responses of the CIC filter compensated with these compensators. The minimax compensator with three adders reduces the droop slightly worse than the compensator with the lowest complexity. However, both minimax compensators have less complex structures and result in better compensations compared to the maximally flat counterpart.

B. Wideband Compensators

Recently, the interest in wideband compensation has been increasing. The efficient wideband compensation can be obtained by using the compensators with M>3 coefficients. The multiplierless maximally-flat compensator with M=5 coefficients has been described in [11]. In the paper referred to, the authors elaborate that 15 adders are necessary for the compensation of the CIC filter with N=5 and R=32. However, our compensator with five coefficients, which is obtained for K=12, P=4, and ω_c=0.5π, needs 14 adders. Figure 5 shows the magnitude responses of the CIC filter compensated with the minimax and with the maximally flat compensator. It is clear that

minimax compensator with less number of adders yields much better wideband compensation.

To obtain more efficient wideband compensation, the compensator with M=7 coefficients should be used. For illustration, the CIC filter with N=5 and R=1024 is compensated over the band $|\omega|\le 0.5\pi$. Figure 6 shows the obtained magnitude response. The coefficients with P=4 are specified, resulting in the compensator structure with 19 adders, and the compensation error less than 0.02dB.

C. Compensators With Lowest Complexity

By setting P=1 in the proposed design, we obtain the compensator with the lowest complexity. Let us consider the compensation of the CIC filter with N=5 and R=32 over the band $|\omega|\le 0.5\pi$. Figure 7 shows the magnitude response of the CIC filter compensated with the lowest-complexity compensator with M=7 coefficients, whose structure has seven adders. In the figure, it is also shown the response compensated by the minimax compensator

with three coefficients, which employs the same number of adders. Since both compensators have equal complexity, similar improvement is expected. The lowest-complexity compensator reduces the passband droop to 0.5dB, what is slightly higher than the droop obtained by the three-coefficient compensator. However, outside the passband it has a high roll-off characteristic, which is often desirable.

IV. Conclusion

The design of minimax CIC compensators over the SPT coefficient space has been presented. The optimum compensator's coefficients are obtained by using the global optimization based on the interval analysis. It is illustrated that such an optimization enables the design of the compensators with high number of coefficients, as well as the compensators resulting in efficient compensation over a wide band. Compared with the known CIC compensators with SPT coefficients, the presented compensators generally result in a better compensation and a lower complexity.

Abstract— This paper describes the educational method for selection of semiconductor switches based on the results of simulated behaviour of the converter circuit with ideal switches. The current-voltage relations on the converter circuit ports and the converter topology determine the requirements for the static and switching characteristics of semiconductor switches. Selection of the switches is illustrated with examples of a full-bridge rectifier with a resistive-inductive load, a buck converter with a resistive-inductive load and a resonant inverter.

I. INTRODUCTION

Educational literature concerning power electronics, from its very beginning in the ninety-twenties and mostly also until today, introduces the student into power electronics through analysis of the power converter circuits (i.e. from specific towards general) [1−7]. It starts from the simple converter circuits (e.g. single phase line-frequency diode rectifiers), and ends with the more complex inverter circuits (e.g. PWM-inverters). Such textbooks are suitable as introduction to circuits design, but not as introduction to the methodology (the systematic study of methods that are, can be, or have been applied within a discipline) for power electronics. Our experience is that even conscientious students soon forget the voltage-current relations and the related formulas.

The described approach is based on postulating the topology and function of the converter circuit (rectification, DC/AC conversion, DC conversion and AC conversion). It is shown that by using the same topology (e.g. bridge connection), but by different methods for controlling the switches, various functions of the converter circuit can be achieved. It is also shown that the selected semiconductor switch does not need to have all characteristics of the ideal switch and that the desired function, with the same topology, can be achieved by different semiconductor switches. By using this approach, the student will note the common characteristics of the converter circuits of the same topology and will learn to think by using the methodology of power electronics. Such approach builds upon the approach in the textbook [7], where it is clearly shown that all applications of power electronics share the common basics.

At the starting level of analysis of operation of the converter circuits by using computer simulation programs it is beneficial to use the ideal (mechanical) switches instead of the models of semiconductor switches. This shortens the time for simulation, avoids the need to define parameters for the semiconductor switches model, simplifies modelling of the controlling circuit, and simplifies the analysis of the obtained results. The results of the simulation are the current-voltage relations of the ideal switches. These current-voltage relations can be used to make conclusions about the semiconductor switches which can be used in the real analysed converter.

II. DEFINITIONS OF SEMICONDUCTOR VALVES AND SEMICONDUCTOR SWITCHES

A semiconductor valve or component is a non-operational whole, which only together with the driving circuit and over-current and overvoltage protection and cooling arrangement, forms an operational whole - semiconductor switch.

Semiconductor switch devices are divided into non-controllable, semi-controllable and fully controllable. The non-controllable devices, e.g. diodes, switch when the voltage polarity at its ports changes. The semi-controllable devices, e.g. thyristors, switch on according to the control signal on the gate, and switch off when their current drops to zero. The fully controllable devices, e.g. transistors, switch on and off according to the control signal applied to the control electrode.

The ideal switch is fully controllable, i.e., it can be momentarily switched on or off by an appropriate (logical) controlling signal at wish. The ideal switch conducts current in both directions and holds both voltage polarities. The ideal switch is an element without any losses, i.e. a product of voltage and current in any time is equal to zero, Fig. 1.

The semiconductor switch has only some of the characteristics of an ideal switch.

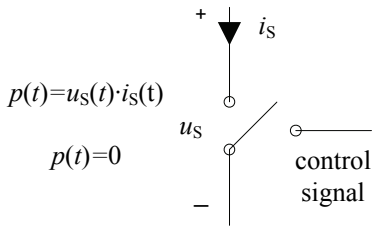

Fig. 1. Model of an ideal switch

III. STATIC MODELS OF SEMICONDUCTOR SWITCHES AND OPERATING QUADRANTS

Static characteristics of semiconductor switches are modelled by idealised and ideal models. Fig. 2 shows the idealised and ideal models for the static characteristic of a diode switch. The idealised model represents the diode static characteristic in the forward region by using threshold voltage U_{th} and dynamic resistance R_d. The reverse characteristic of the diode is modelled with a large enough resistance R_{bl}.

The ideal model for the static characteristics is determined by the borders of the operating quadrants. Operating quadrants for the semiconductor switch are the quadrants on the graphical representation of the voltage polarity that a device can hold at it's ports and the direction of the current through it's ports. A diode switch can hold reverse voltage and conduct current in one direction. According to that, a diode switch fits in the second operating quadrant, Fig. 3 a). A thyristor switch can hold voltages of both polarities and conduct current in one direction; hence its operating quadrants are the first and the second, as shown in Fig. 3 b). A transistor switch can hold voltage of one polarity and conduct the current in one direction; hence its operating quadrant is the first, as shown in Fig. 3 c).

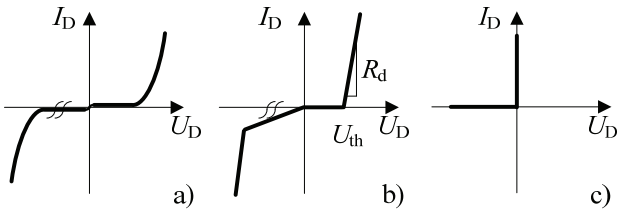

Fig. 2. Static characteristics of a diode switch: a) real, b) idealised, c) ideal model

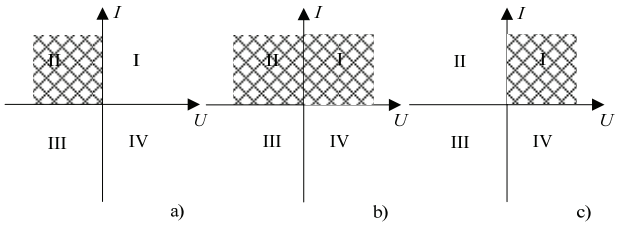

Fig. 3. Operating quadrants of a) diode, b) thyristor, c) transistors

The operating quadrant is non-controllable if the switch can neither switch on nor switch off in that quadrant by a control signal. The operating quadrant is semi-controllable if the switch can only switch on in that quadrant, and fully controllable if the switch can switch both on and off in that quadrant. For example, the second operating quadrant for diode switch is non-controllable, since a diode cannot switch off or switch on under influence of the control signal. The first operating quadrant for a thyristor switch is semi-controllable, since in that quadrant the thyristor can switch on, but cannot switch off, while the second thyristor quadrant is non-controllable. The first operating quadrant for a transistor switch is fully controllable, since the transistor can both switch on and switch off in that quadrant by a control signal. Table I shows the operating quadrants and controllability for the basic semiconductor switches.

If the required operating quadrants cannot be achieved using only one semiconductor switch, combinations of basic semiconductor switches (called hybrid semiconductor switches) is used. A serial connection of a transistor and a diode makes a switch that conducts current in one direction and holds voltage of both polarities. This is a one-directional current and a bipolar voltage semiconductor switch. An anti-parallel connection of a transistor and a diode makes a switch that conducts current in both directions and holds the voltage of one polarity. This is a bi-directional current and a unipolar voltage semiconductor switch. Table II shows the hybrid semiconductor switches by controllability and operating quadrants.

IV. METHOD FOR SELECTION OF SEMICONDUCTOR SWITCHES

Method for selection of semiconductor switches is based on the current-voltage relations of ideal switches that form a simulated converter circuit and on the analysis of its switching characteristics.

To achieve the desired converter function different topologies can be used. For example, a single-phase thyristor bridge circuit and a single-phase thyristor circuit with neutral point perform the function of rectifying with the full-wave rectified waveform on the resistive-inductive load. Note that the function of the converter is also determined by the switching logic (e.g. phase-controllable converters) and switch implementation (e.g. buck and boost converter), other than the converter topology.

After selection of the topology of converter circuit with ideal switches (e.g. single-phase bridge connection), the desired circuit function is selected (e.g. rectification) at given load (e.g. resistive-inductive). The reference direction of the current and the reference voltage polarity are assigned to the ideal switch. If the switch is anticipatively unidirectional, the direction in which the switch conducts the current corresponds to the reference current direction. If the switch is anticipatively unipolar, the polarity in which the switch does not conduct the current corresponds to the negative reference voltage polarity.

The waveforms of the voltages and currents of an ideal switch, (voltage-current loading) obtained by the simulation determine the operational quadrants of the switches. By using data from Tables I and II it can be concluded which semiconductor switches can be considered, regarding their static and circuit characteristics.

It is desirable to select the simplest possible switch, since an increased number of semiconductor devices that make the switch means an increased complexity of the gate drive and losses.

TABLE I:

OPERATING QUADRANTS AND CONTROLLABILITY OF BASIC SEMICONDUCTOR SWITCHES

Valve	**Symbol**	**Controllable operating quadrants**	**Semi-controllable operating quadrants**	**Non-controllable operating quadrants**
Diode		-	-	II.
Thyristor		-	I.	II.
Triac		-	I., III.	-
Inversely conductive thyristor		-	I.	IV.
MOSFET		I.	-	-
IGBT		I.	-	-

TABLE II:

OPERATING QUADRANTS AND CONTROLLABILITY OF HYBRID SEMICONDUCTOR SWITCHES

Switch	**Symbol**	**Controllable operating quadrants**	**Semi-controllable operating quadrants**	**Non-controllable operating quadrants**
Serial connection of diode and transistor		I.	-	II.
Anti-parallel connection of diode and transistor		I.	-	IV.

V. EXAMPLES FOR SELECTION OF SEMICONDUCTOR SWITCH DEVICES

A. Single-phase bridge converter

A scheme of the simulated circuit is shown in Fig. 4. On the input to the converter there is a source of sinusoidal voltage. The load is resistive-inductive. To obtain a phase-controllable rectified voltage waveform on the load, switching pairs S1, S4 and S2, S3 switch in counter-stroke. The scheme also shows the reference directions of the currents and the reference polarities of the voltages on switches S1, S2.

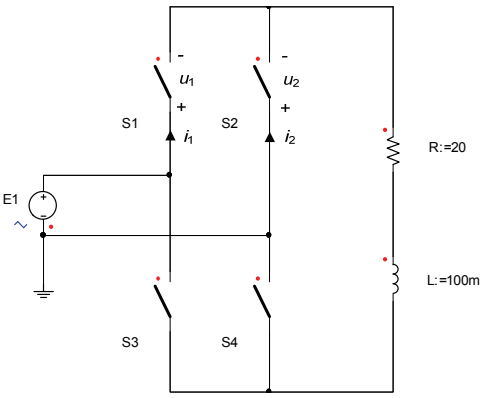

Fig. 4. Simulation model of the single-phase bridge converter

Fig. 5. a) shows the load voltage waveform for the control angle $\alpha = 45°$. Fig. 5 b) shows the load voltage waveform for the control angle $\alpha = 135°$ and a current source load. For the control angle $\alpha > 90°$. the average output voltage U_i is negative.

Fig. 6 shows the voltage and current waveforms of S1, S4 and S2, S3, for $\alpha = 45°$. Analysis of the current-voltage relations of the switches shows that the switches conduct the current in one direction and that they hold a positive and negative voltage. An analysis of the switching characteristics shows that the switches switch on the positive current when the voltage is positive and that they take on the negative voltage when switched off. Due to the source voltage, commutation of the load current occurs from one switch pair to the other.

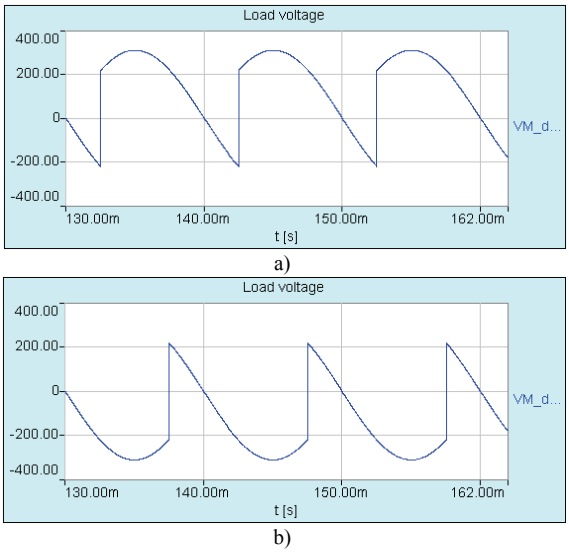

Fig. 5. Load voltage waveforms for the control angle

a) $\alpha = 45°$, b) $\alpha = 135°$

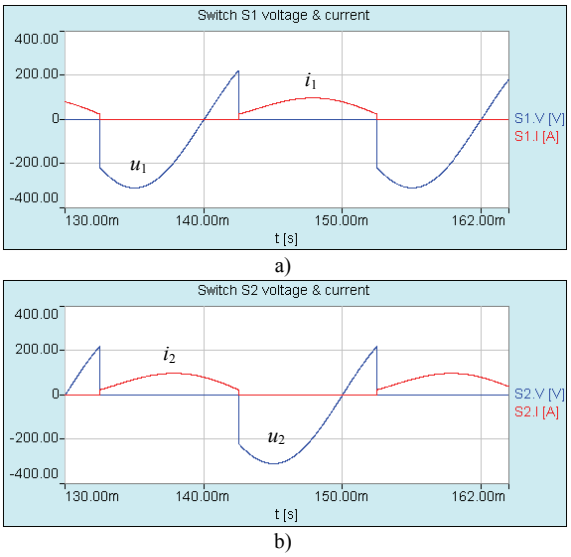

Fig. 6. Current and voltage waveforms for a) switches S1, S4, b) switches S2, S3

By comparing the characteristics of the ideal models of basic semiconductor switches from Table I it can be concluded that the switches can be achieved by using thyristors, Fig. 7. If it is sufficient that the load voltage is controllable and unipolar, diodes can be used instead of TH1 and TH4. If it is sufficient that the load voltage is constant and unipolar, diodes can be used instead of all thyristors.

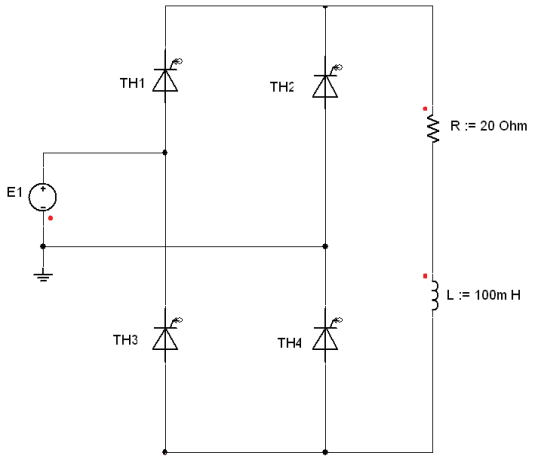

Fig. 7. Single-phase bridge converter with the thyristors

B. Buck converter

A scheme of the simulated circuit is shown in Fig. 8. Switches S1 and S2 operate in counter-stroke. When S1 is switched on, the voltage on the input to the *LC* filter is equal to the input voltage. When S1 switches off, S2 is switched on and the voltage on the input to the *LC* filter is equal to zero. The scheme also shows the reference directions of the currents and the reference polarities of the voltages on switches S1 and S2.

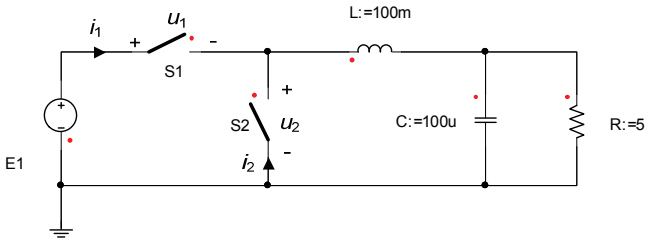

Fig. 8. Simulation model of a buck converter

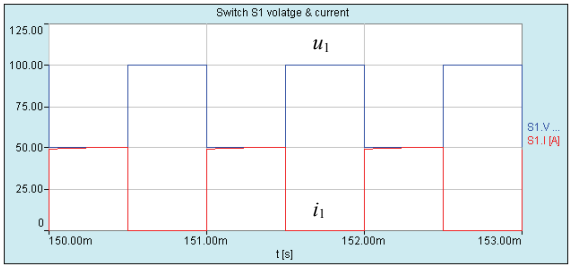
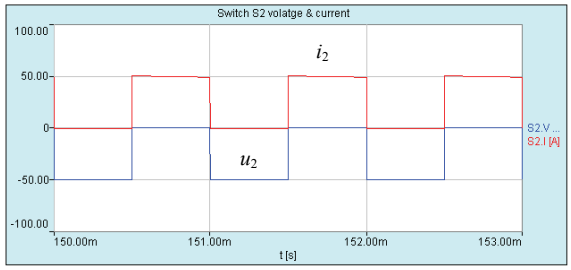
Fig. 9 a) shows the waveforms of voltages and currents of S1 and Fig. 9 b) shows the waveforms of voltages and currents of S2. An analysis of the current-voltage waveforms of the switches shows that switch S1 conducts the positive current and holds the positive voltage. Switch S2 conducts the positive current and holds the negative voltage. An analysis of the switching characteristics shows that S1 switches on and off the positive current when the voltage is positive. S2 switches on the positive current, and when switched off, it holds the negative voltage. Switch S1 is a fully controllable switch. When S1 switches off, due to the commutation caused by the inductive load, S2 switches on. By comparing the characteristics of ideal models of semiconductor switches from Table I, it can be concluded that S1 can be implemented using some of the transistors, e.g. MOSFET, and S2 by using a diode, Fig. 10.



a)



b)

Fig. 9. Voltage and current waveforms of a) switch S1, b) switch S2

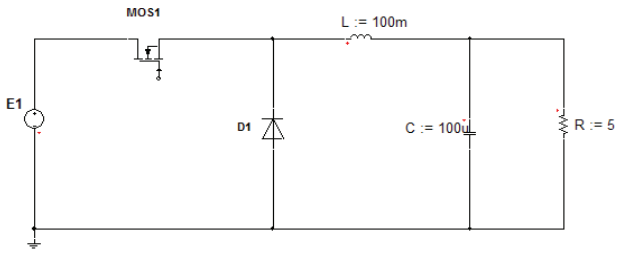


Fig. 10. Buck converter with MOSFET and diode

C. Resonance inverter with voltage input

A scheme of the simulated circuit is shown in Fig. 11. At the input side of the converter is a DC voltage source. The load is a serial oscillating circuit. To obtain sinusoidal voltage on the load, i.e. on the resistance *R*, switches S1 and S4 and switches S2 and S3 are operating in counter-stroke, at a frequency slightly higher than the resonant frequency of the oscillating circuit.

Fig. 12 a) shows the waveforms for the load voltage and current. Fig. 12 b) shows the voltage and current waveforms for S1 and S4. An analysis of the current-voltage waveforms of the switches shows that the switches conduct the current in both directions and hold the positive voltage. An analysis of basic switching characteristics shows that the switches switch on the negative current and that when they switch off, they hold the positive voltage. Comparing the characteristics of the ideal models of basic semiconductor switches from Table I, it can be concluded that there exists no such basic semiconductor switch. The bidirectional current switch is achieved by e.g. IGBT and an anti-parallel diode, as shown in Fig. 13.

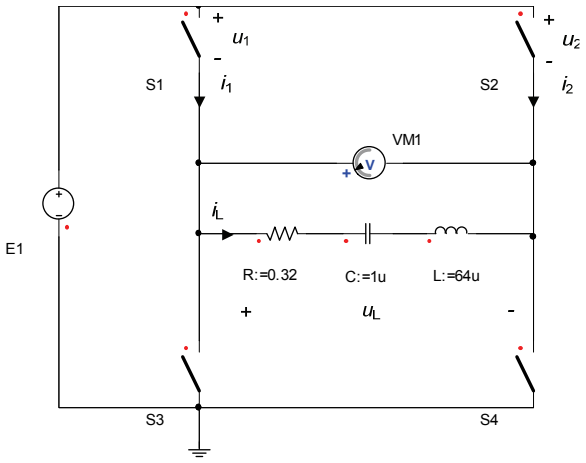

Fig. 11. Simulation model of a resonant inverter

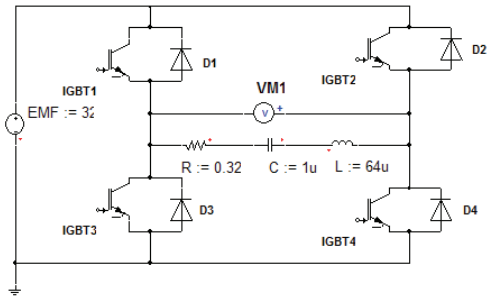

Fig. 13. Resonant inverter with IGBTs and diodes

VI. Conclusion

The paper has shown an educational method for the selection of semiconductor switches for power electronic converters. The switches are selected according to its static and switching requirements. In most cases semiconductor switches will have just some of the characteristics of an ideal switch. It has been shown that the selection of the switches does not depend only on the topology of the converter circuit, but also on converter function. It has also been shown that the load type influences the switching characteristics.

** Faculty of Electrical Engineering and Computing/Department of Electric Machines, Drives and Automation, Zagreb, Croatia
tcihak@koncar-institut.hr

Electrochemical dual layer capacitors, also known by their market names Supercapacitors and Ultracapacitors are perspective technology for many uses, for instance in power saving circuits for electric propulsion systems, short-term energy storage systems, systems for extending battery lifetime and other similar uses. Although they can be used connected directly to a power converter DC link, in most cases they are connected to the DC link through a separate power converter. In use, such an EDLC and power converter assembly, due to EDLC specifics, must reliably operate in numerous operating points, unlike a typical power electronic converter. Such a power converter operation entails many control issues. Some of them are considered in this paper.

I. INTRODUCTION

A component that enables storage of energy, a capacitor, is known for several hundred years, ever since a Leyden jar has been invented. As a component, in essence two metal plates separated by dielectric material, capacitor has not been changed from the day of its invention. In 1957, an innovation to capacitor technology has occurred. H. E. Becker [2] has filed for an invention of electrochemical dual layer capacitor. In electrical view, this component is also a capacitor, but in comparison with previously known capacitor types, is has much higher capacity, up to several orders of magnitude. In consequence, this innovative component has extremely high specific power rating and specific energy rating in the same order of magnitude as, in that sense, weakest batteries.

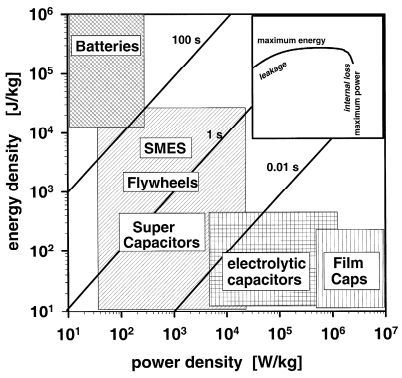
These properties enable electrochemical dual layer capacitors, EDLC in further text, to be used as an energy buffer located in the DC link in high power systems, a supplemental source in systems with battery or similar power source, and in some cases EDLCs can be the primary power source. Properties of EDLCs are based on a phenomenon [1], which can be explained in short as follows. If an electrode is submerged into an electrolyte, on the interface between electrode and electrolyte (interface in further text) charge separation occurs in immediate vicinity of the interface. On electrode surface an excess (or deficiency) of electrons appears. To achieve neutrality, non-balanced state is brought back to balance by electrolyte ions. For such a system, charge separation distance is equivalent to the dielectric thickness of a classic capacitor. If using two electrodes, at each of the interfaces an equivalent to the capacitor appears, and the resulting device is equivalent to a series connection of two capacitors. EDLC material type and charge separation distance are responsible for high EDLC capacities [17].

II. EDLC AS A POWER SOURCE

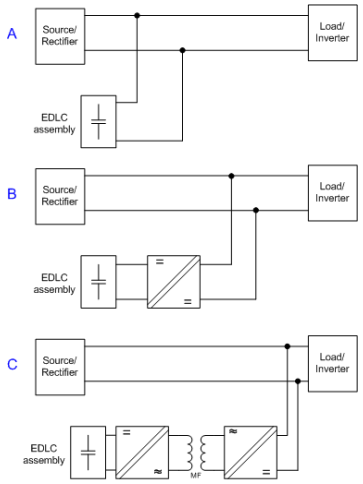
Based on the previously emphasized properties, one can see an EDLC as a potential power source, albeit a "weak" one compared to, for instance, batteries. This "weakness" must be properly defined, and for that matter a Power-Over-Energy graphs (specific values over volume, so called Ragone plots) are used [8][11]. Example is shown in Picture 1. From this picture it can be seen that typical batteries have a very high energy density for a given volume but a rather low specific power. This can be interpreted otherwise. Due to high internal impedance, high current loads, especially peak power transients, are not possible because of a resulting battery voltage drop. Such a behavior is not specific attribute only of batteries, but also of typical fuel cells and other power sources with high internal (real or equivalent) impedance, such as tram DC voltage grid. EDLCs on the other hand act in the same way as conventional capacitors, meaning that they can supply a load with high power in a short amount of time and vice versa. Such operation behavior makes them a natural complement to previously mentioned power sources. On the basic level, they can be used in a passive way, connected in parallel to the power source [12], as shown in A on Picture 2. Such type of connection can be easily implemented but comes with several problems, as for instance initial charging and cell voltage balancing, which are beyond the scope of this paper.

$$\Delta E_C = E_C(U_1) - E_C(U_2) = \frac{C}{2} \cdot \left(U_1^2 - U_2^2\right) \qquad (1)$$

But, more importantly, not much of the total amount of the stored energy can be used. In a simple system described previously, maximum energy requirement occurs during the acceleration of the drive (or sudden change of load in a static system). During this time, according to (1), EDLC system can supply only energy



Picture 1 : Power sources Ragone plot (taken from [10]).

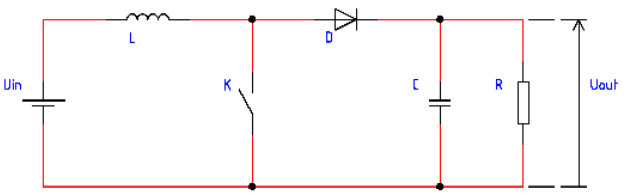


Picture 2 : EDLC connection topologies.

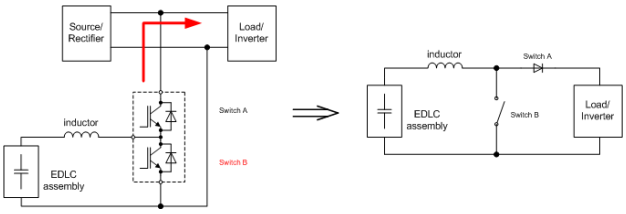
equal to voltage drop during the current spike. This problem can alleviated using a power converter circuit, as shown in B or C in Picture 2.

III. POWER CONVERTER FOR AN EDLC SYSTEM

According to previous, it can be said that to extract more stored energy from EDLC, a higher voltage difference between EDLC and load must be present. This is accomplished using power converter which, according to previously stated, must be of voltage boosting type. Basic boost converter is shown in Picture 3. Although required power components for such a converter can be found as a complete module, for high power circuits (on the order of several kilowatts up to several hundred kilowatts) and voltage levels of hundreds of volts, it is practice, due to price and component availability, minimization of number of components and simplification of control circuits to combine both EDLC discharging (boost) circuit and EDLC charging (buck) circuit into one circuit as shown in Picture 4. It should be mentioned that there are other, more complex converter topologies that can be used, but for high power circuits they are rarely used. One other distinctive feature of a power converter combined with EDLC assembly is that EDLCs do not necessarily have to be on the same voltage level when fully charged as a DC link (or load) that is to be supplied with energy. Control systems for such power converters range from simple hysteresis control to extensive neural network based systems. Since each of these control



Picture 3 : Basic boost converter.



Picture 4 : Dual IGBTmodule as a boost converter.

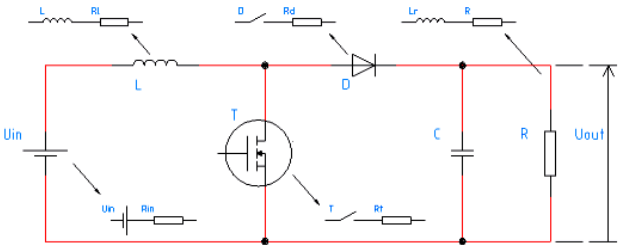
methods has its problems and features, and each of them can be successfully utilised it is up to the system designer to choose the most appropriate control system.

IV. EDLC AND POWER CONVERTER MODEL

As the most appropriate control system for present and future work, a linear control system with PI(D) regulators is to be used. Several reasons leveraged into using such a system. Namely, simplicity of the system, widely known problems and means for resolving them, and available means of setting the operating points in adequate or optimal way, each available as practical recommendations and thorough theoretical basis [5][6]. Also, since future work will deal with practical implementation of proposed systems, a relatively simple control system must be used due to hardware and software limits of the planned platform. For this paper, control system will deal only with EDLC discharging, as for the EDLC charging, a different control method will be used. According to previous, a boost converter shown in Picture 5 will be used as a switching model. For system analysis such a model must be converted into linearised model which can be used for analysis using bode plots and controller synthesis.

$$D = 1 - \frac{U_{IN}}{U_{OUT}} \Rightarrow D(U_{IN}) = 1 - \frac{U_{IN}(t)}{U_{OUT}} \qquad (2)$$

First step in this process is converter analysis in its two states (power switch on and off). It should be stated that at this point, all of the components that differentiate the model containing ideal components shown in the Picture 3 from the real-world model should be implemented, as this will have impact on the realized models. Some of these parameters can be ignored because of the minimum impact on the control system as will be shown later. One parameter that cannot be ignored is equivalent series resistance of the inductor (ESR in further text). Every practical inductor realization will have a notable resistance, both absolute and relative to the other components. Through analysis it can be seen that active power electronic components, in this case switches (either MOSFETs or IGBTs) and diodes are also non-ideal components and in many cases these differences from



Picture 5 : Used models of non-ideal components.

ideal components are considerable and therefore some of their properties must be implemented into the model [13][14]. This problem is not trivial if the intention is to create a universal model, non dependent on the switch type or diode type (Fast silicon diode, SiC diode or other).

For the used model switch and diode non-ideal characteristics are modeled only with the on-state resistance across them, as shown in the Picture 5. Other models were tested but not used during control system synthesis as for particular implementation differences were negligible. As for the passive elements, smoothing capacitor at the load side shown in Picture 5 can be broken down further, but as the load type (inverter input, motor or other) is not to be defined it was not implemented. For the system in two switching states, using Kirchhoff rules, a set of equations given in the state space form, according to (3) can be created. A set of equations describing the system during the switch on-state, and another describing the rest of the switching period are created. For further analysis, these sets of matrices are combined according to (4). Stationary operating points can be found if variable derivation in (4) equals zero, as shown in (5). Using these equations, duty cycles, different to that of an ideal boost converter, for stationary operating point can be found. Of course, if introduced resistances equal zero, equation reduces into (2).

$$\begin{aligned} \dot{x} &= A\cdot x + B\cdot u \\ y &= C\cdot x + D\cdot u \end{aligned} \tag{3}$$

System transfer function is generated around a specific operating point and is valid for small signal disturbances only. System variables in equation (4) are substituted with a sum of stationary member and time dependant member (signal perturbation around stationary value) according to (6). These substitutions are done for currents, voltages and duty cycle in (4). Products of signal perturbation pairs, stationary value pairs and stationary value derivations equal zero. After rearranging a new set of matrix equation that define the system are given according to (7). The system has two excitations, i.e. two inputs and therefore two transfer functions are obvious. These are given with (8) and (9). They are calculated from the (3) by applying Laplace transformation on these equations. Transformed system gives a simple computation method, but care should be taken since the matrix B changes depending on the transfer function input. Resulting functions are given with (10) and (11). If this method is applied at the model that does not involve on-state resistances it can be seen that function (8) does not change, but only (9). Therefore, introduced non-ideal properties of semiconductor elements will have no influence on the form of (8).

$$\begin{bmatrix} \dot{i}_L \\ \dot{u}_C \end{bmatrix} = \begin{bmatrix} -\dfrac{R_L + R_T D + R_D(1-D)}{L} & -\dfrac{(1-D)}{L} \\ \dfrac{(1-D)}{C} & -\dfrac{1}{RC} \end{bmatrix} \cdot \begin{bmatrix} i_L \\ u_C \end{bmatrix} + \begin{bmatrix} \dfrac{1}{L} \\ 0 \end{bmatrix} \cdot \begin{bmatrix} u_{IN} \end{bmatrix} \tag{4}$$

$$\begin{aligned} 0 &= A\cdot x + B\cdot u \\ y &= C\cdot x + D\cdot u \end{aligned} \tag{5}$$

$$x = X + \tilde{x} \tag{6}$$

$$\begin{bmatrix} \dot{\tilde{i}}_L \\ \dot{\tilde{u}}_C \end{bmatrix} = \begin{bmatrix} -\dfrac{R_L}{L} & -\dfrac{(1-D)}{L} \\ \dfrac{(1-D)}{C} & -\dfrac{1}{RC} \end{bmatrix} \cdot \begin{bmatrix} \tilde{i}_L \\ \tilde{u}_C \end{bmatrix} + \begin{bmatrix} \dfrac{U_C + I_L(R_T - R_D)}{L} \\ -\dfrac{I_L}{C} \end{bmatrix} \cdot \begin{bmatrix} \tilde{d} \end{bmatrix} + \begin{bmatrix} \dfrac{1}{L} \\ 0 \end{bmatrix} \cdot \begin{bmatrix} \tilde{u}_{IN} \end{bmatrix} \tag{7}$$

$$\begin{bmatrix} \tilde{u}_{OUT} \end{bmatrix} = \begin{bmatrix} 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} \tilde{i}_L \\ \tilde{u}_C \end{bmatrix} + \begin{bmatrix} 0 \end{bmatrix} \cdot \begin{bmatrix} \tilde{d} \end{bmatrix} + \begin{bmatrix} 0 \end{bmatrix} \cdot \begin{bmatrix} \tilde{u}_{IN} \end{bmatrix}$$

$$F_{uoutuin}(s) = \frac{\tilde{u}_{OUT}(s)}{\tilde{u}_{IN}(s)} \tag{8}$$

$$F_{uoutd}(s) = \frac{\tilde{u}_{OUT}(s)}{\tilde{d}(s)} \tag{9}$$

Bode plots (magnified around the maximum magnitude point) of the $F_{uout\,d}(s)$ are given on Picture 6 to show the expected influence. In these examples switch and the diode values of R_d=50mΩ and R_t=20mΩ were used. Because of the shown difference and the form of the function (11), simplified model was used for control system synthesis. These functions are shown in Picture 7. For the confirmation of the results, a switched model was created in *MATLAB/Simulink*. A schematic of this model is shown on Picture 8. Testing was done by parallel step excitation on the switched model and the transfer functions. Confirmation results are shown in Picture 9.

$$F_{uoutd}(s) = \frac{(1-D)U_C - I_L\left(sL + R_L + (1-D)(R_D - R_T)\right)}{s^2LC + s\left(\dfrac{L}{R} + R_LC\right) + \left(\dfrac{R_L}{R} + (1-D)^2\right)} \tag{10}$$

$$F_{uoutuin}(s) = \frac{(1-D)}{s^2LC + s\left(\dfrac{L}{R} + R_LC\right) + \left(\dfrac{R_L}{R} + (1-D)^2\right)} \tag{11}$$

Picture 10 shows that created transfer function are correct only around the computed operating points and

therefore control system will have adequate performance only around this operating point.

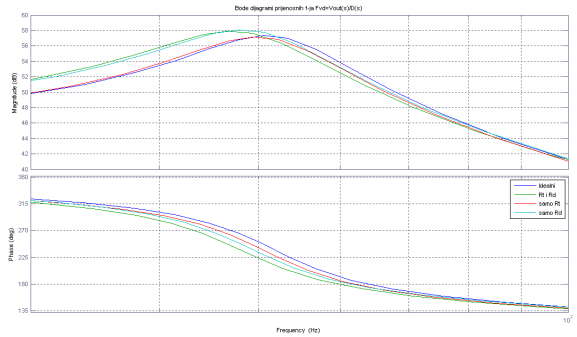
V. CONTROLER DESIGN AND MODIFICATIONS

For control system synthesis, several theoretical and practical methods are available. As a basis for this system, a method using practical recommendations was used [5][6][7]. This approach was used as it is most probable in future practical implementation. Also, such an approach results with a non-critical system setup. Control system was specified to have gain margin in range of 5dB and 15dB and phase margin in the range between 40° and 60°. All relevant points were read out from the Picture 7 using MATLAB integrated tools. Using read points and (12), where for ω_{OP} converter's peak amplitude frequency was chosen, a regulator was created. Several gain margin values were tested and as a representative values, 5dB and 10dB settings were used. Resulting system is analysed as Picture 11 shows. Regulator is implemented into the switching model, according to [6] as the Picture 12 shows.

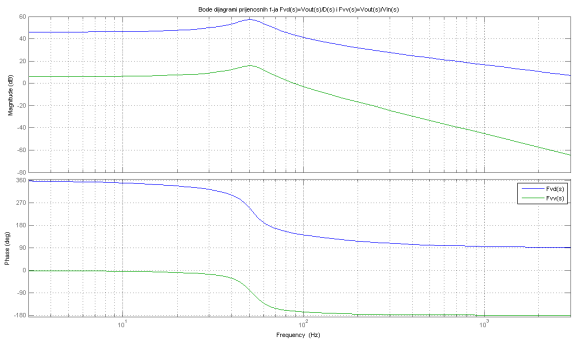
$$F_{PI}(s) = K_P + \frac{K_I}{s} = K_P + \frac{K_P \cdot \omega_{op}}{s} \qquad (12)$$

First implementation was done directly as the literature suggests. Such regulator form is only useful for educational purposes as practical limits of the system, such as saturation, are not taken into account. Basic system testing was done using an ideal voltage source. System is first brought into stationary operating point, and step-change of the input voltage is then executed. Picture 15 shows a system responses for system with 14dB gain margin. Reference (output) voltage is 200V, input voltage has a step change to 100V and later to 50V. 2Ω load was used. As previously pointed out, shown controller design is straightforward and can be used for typical boost converters where input conditions do not change by a great degree. A system that involves EDLCs necessarily has input conditions that can change by a great degree. More precisely, with EDLC discharge system transfer functions change by a noticeable degree. This is in contrast with operating conditions presumption made during the switch model linearization process. As a consequence, controller settings will be necessarily non-optimal. This can be especially noted for some settings, for instance if the system speed is of essence. This can be clearly seen in Picture 16. Here, a Picture 15 and Picture 16 show the same system with two controller settings. Controller is set for a stationary operating point where D=0.5 (input voltage of 100V). Response is adequate if input is 100V for both settings, but when input voltage changes to 50V system becomes unstable for a "fast" controller as the system changed in a great degree. Clearly, in this case both speed and stability cannot be obtained.

But, if the system transfer function can be found throughout the operating area, then optimal controller settings can be found for any point inside this area. For particular system, transfer functions were found in several distinctive operating points. For each of the operating points, controller settings were calculated, using (12) and tested. Resulting controller settings were then set up as simple matrices. *MATLAB/Simulink* controller was then

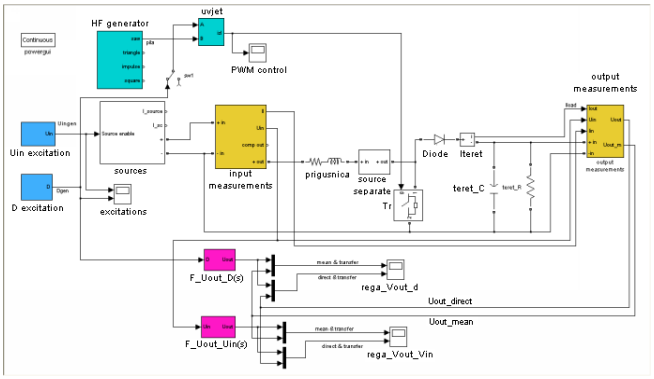


Picture 6 : Comparison of component influence on $F_{uout\ d}(s)$.

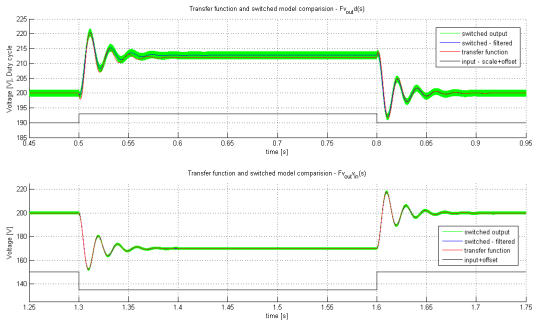


Picture 7 : Bode plots of $F_{uout\ d}(s)$ and $F_{uout\ uin}(s)$ of the used model.

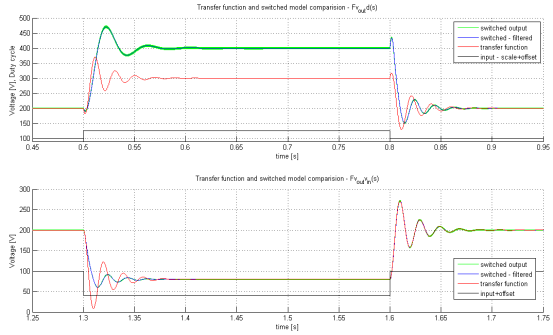
modified using look-up tables (part of this controller containing this modification is shown in the Picture 13), and the matrices were then set as their inputs and outputs. Look-up tables were then set up for linear interpolation between calculated points. This system was tested using the same input change and results evaluated. Acquired results (not shown, see further text), along with tests in other operating points, confirm the hypothesis that such an adaptive system will be stable throughout the planned operating range. Further modification is possible by changing linear interpolation on calculated regulator parameters with explicitly found functions that define the parameter change throughout the operating range. This modification was done using the *MATLAB* curve fitting tool. Several function types and settings were tested. Acceptable results were found for more than one function type. An example, employing polynomial and exponential functions is shown in Picture 13. Functions were tested using the system in Picture 12, and the results are shown in the Picture 17. As the results are same or better than with linear extrapolation, previous results are not show. Except for this modification that takes into account the specifics of the boost converter connected to the EDLC system, a control system modification that takes EDLC structure specifics was implemented. More specifically, EDLC analysis shows that some of its parameters must not be omitted in control system design. One of the parameters with great impact on system behavior is EDLC internal resistance. Literature [15][16][17] and EDLC specifications [18][19] show that EDLCs, although much lower than typical batteries, have unusually high internal resistance in comparison with other capacitor types. Therefore, even the simple EDLC models used in simulations must employ the EDLC ESR (or, if applicable, equivalent parallel resistance). Namely, it causes



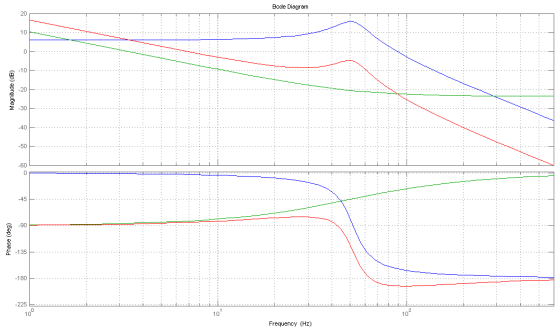
Picture 8 : Parallel testing of switching and linearised model.



Picture 9 : Results of parallel model testing.

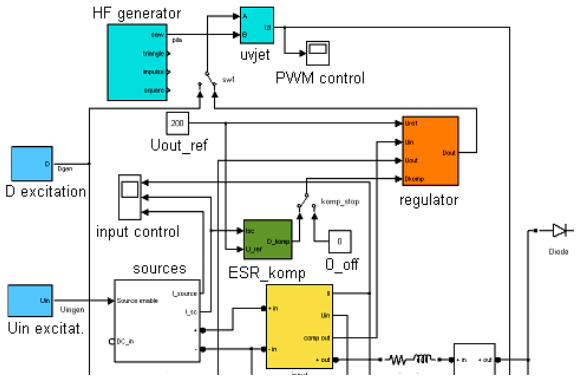


Picture 10 : Function behaviour on large input signal change.

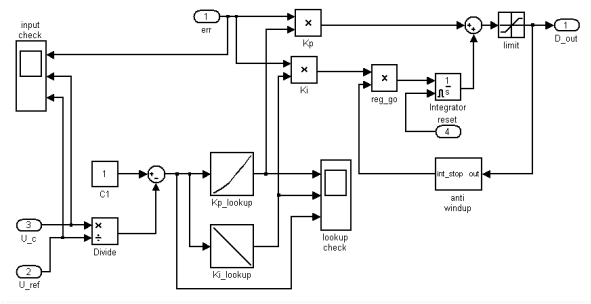


Picture 11 : Transfer functions and regulator (10dB amp. margin, red).

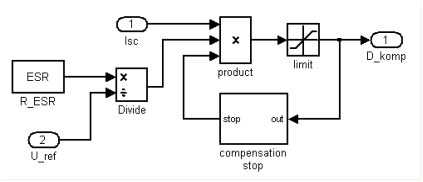
a noticeable voltage drop when load is connected to EDLC (i.e. when discharge occurs). This can be observed in tests of commercially available EDLCs [20], and it is commonly refered to as an EDLC resistive voltage drop. For simulation purposes and for confirmation of previous control system modification performance, an EDLC model was needed. Several models were tested [17] and a simple capacitor-resistor model was found adequate for this particular system. Previous converter model was



Picture 12 : Control system, including compensation.



Picture 13 : Adaptive regulator.

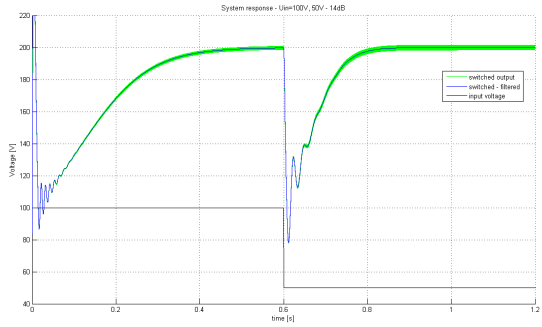


Picture 14 : Compensation block.

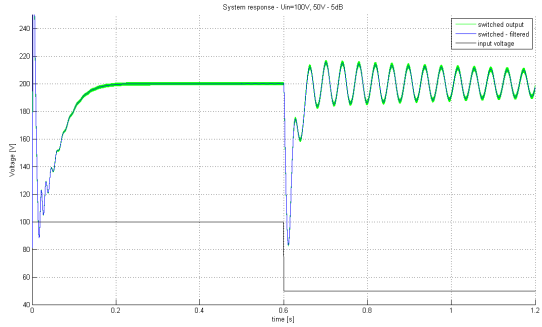
modified by adding EDLC model parallel to ideal voltage source. Resistive voltage drop can be seen both in the open loop system and the closed loop system as shown in the Picture 18. In results shown, for clarity purposes, high EDLC resistance was used (100mΩ). Through model analysis, it can be seen that the resistive voltage drop is proportional to discharge current. This voltage drop, defined with (13) shows a possibility to compensate it through a controller design. Such compensation, as it can be defined explicitly, should be incorporated as a feedforward controller component [4]. This was done as a separate block as shown in the Picture 14.

$$D_{comp} = 1 - \frac{U_C}{U_{OUT}} + \frac{R_C \cdot I_c}{U_{OUT}} = D_{reg} + \frac{R_C \cdot I_c}{U_{OUT}} \qquad (13)$$

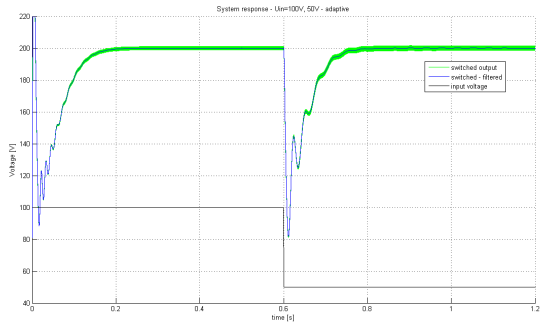
Simulation was done with the system parameters which achieve results as in Picture 18. Results incorporating ESR compensation are shown in Picture 19. Care should be taken in interpretation of this results and their implementation in a practical converter controller. Great results are achieved here as the compensator and the model resistance are equal. In practical implementations these will necessarily differ. Each EDLC manufacturer specifies an ESR value [18][19], which is given as a range of values which changes with capacitor ageing. Moreover, ESR values are given for very specific test conditions which are non-uniform. In practice, it can be shown that, due to EDLCs highly nonlinear characteristics, calculated



Picture 15 : System response on input voltage step change (slow).



Picture 16 : System response on input step change (unstable).



Picture 17 : System response of an adaptive controller.

ESR values change depending on the charge (discharge) current, temperature, and other [1][20]. Therefore, the compensator should be adjusted not according to datasheet values, but to the measured EDLC resistance values to obtain desired results.

VI. CONLUSION AND FURTHER WORK

Paper shows a quick and practical method for boost converter control system synthesis which includes a procedure for creating usable linearised converter model. Resulting control system is then further expanded to take into account specifics of using EDLCs as power source. Results are presented and it is shown that applied method results with fast, stable and robust system that has practical usability. There is a possibility to measure (evaluate) an ESR value of the EDLC assembly within the control system during the converter start up sequence. Calculated values can be automatically incorporated into the control system. Such measurement, done periodically, can show ageing process of the used EDLC assembly. Investigation of higher-order EDLC model specifics can also be incorporated in the same way. These possibilities will be studied in a future paper.

Wireless Power Transfer for Mobile Phone Charging Device

L. Olvitz, D. Vinko and T. Švedek
Department of Communications, Faculty of Electrical Engineering
Osijek, Croatia
e-mail: dvinko@etfos.hr

Abstract – With an ongoing trend in mobile phone charger standardization, the next step to make the charging process even more user-friendly is to eliminate the physical cable connection between the charger and the mobile phone. To achieve a wireless charging of a mobile phone, a wireless power transfer system must be designed. One such system is presented in this paper. Theory of the wireless power transfer is explained and a functional wireless charger device is realized. Presented wireless charger device has the power transfer capability of around 0.5 W at a maximum distance of 2.5 cm, which is sufficient to charge a regular mobile phone.

I. INTRODUCTION

Cell phone chargers are slowly being standardized mostly because of the power capabilities and wide availability of the USB connectors. This is because cell phones are becoming basically portable computers and need to have a capability to connect with other computers. USB connector offers power and a communication solution. Micro USB connectors on the cell phone end are becoming a standard feature and are making a universal charger possible. Since USB delivers 5 V, all new cell phones are made to be compatible with this voltage level. The lithium batteries work on 3.6 V and because of that the cell phones have their own power converters. This fact makes job of making a universal charger a lot easier.

Currently there is a couple of wireless chargers on the market such as Powemat and Powerbeam [1] but they are not practical and because of that they are only a fancy accessory. Technology used to transfer power from the charger to the cell phone differs with manufacturer. Most common way of transferring energy is inductive coupling, but there is also a direct contact method, infrared power transfer and radio frequency (RF) power transfer [1]. All of them work with limitations specific to technology of choice.

Infrared technology transfers power through light beam using laser diodes. Powerbeam has developed kits ranging from 100 mW, 2.5 W, to 10 W with range of around 10 m [1]. This technology can work but has serious limitations. First, it requires direct line of sight (LOS) between the transmitter and the receiver, the beam can be interrupted and can interfere with IR remote controls. Lastly transferring more than 10W of power with a laser can be very dangerous.

This work was supported by the Ministry of Science, Education and Sports of the Republic of Croatia under project 165-0361630-3049.

RF technology transfers power with radio waves and can also be used. Once more it can interfere with other RF devices and it is limited to a 5 W transmitter with Federal Communications Commission (FCC) regulations [1]. Because of this power limitation on the transmitter, the power transferred to the receiving end is limited to mW range.

Inductive coupling can transfer energy wirelessly and safely. It does not radiate RF, IR signals, and does not need LOS conditions. Because of its benefits this is the technology of choice for wireless power transfer. At the Institute of Technology in Massachusetts Marin Soljačić has successfully transferred 60W of electricity over the distance of 2 m [2].

II. WIRELESS POWER TRANSFER THEORY

To understand how inductive coupling works one needs to understand the theory behind it. Wireless power transfer with inductive coupling is basically using an air core transformer where the primary and the secondary are not fixed together like in a typical transformer. Such power transfer methods are widely used for passive RFID powering [3]-[7], where the needed power is smaller with respect to mobile phone charging.

The schematic of the inductively coupled system used for wireless power transfer is given in Fig. 1. It comprises of a primary and a secondary coil.

Primary side, through which the power is transferred, is shown in Fig. 1 as a power supply (U_S, R_S) and a coil (L_1). The secondary side is formed by resonant circuit (L_2 and C_2) followed by rectifier (D and C_{load}) and resistive load R_{load} representing power consumption of the mobile phone battery charger.

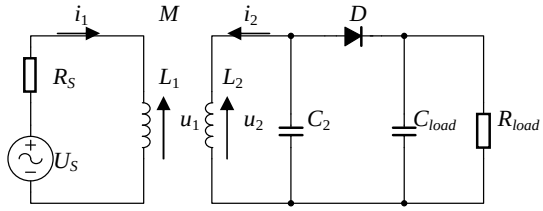

Figure 1. Wireless power transfer system

The power transfer is realized by inductively coupled coils L_1 and L_2 forming loosely coupled air core transformer, whose mathematical formulation is given in (1) and (2).

$$u_1 = L_1 \frac{di_1}{dt} \pm M \frac{di_2}{dt} \tag{1}$$

$$u_2 = L_2 \frac{di_2}{dt} \pm M \frac{di_1}{dt} \tag{2}$$

For the purpose of mathematical analysis the air core transformer is replaced with *T* equivalent circuit (Fig. 2). Resistors R_1 and R_2 are resistive parts of L_1 and L_2 coils.

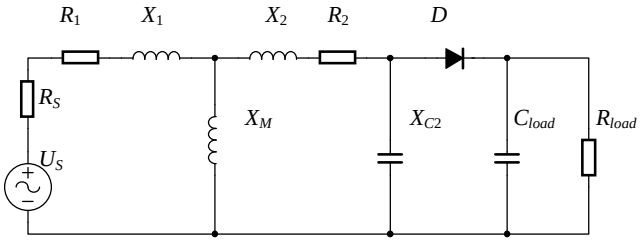

Figure 2. Wireless power transfer system with *T* equivalent circuit for air-core transformer

The values X_1, X_2, X_M and X_{C2} in equivalent circuit are as given in (3)-(6), respectively. This corresponds to a phasor analysis. The aim is to replace the wireless power transfer system with Thevenin voltage and Thevenin impendance. By so doing the mathematical formulation of the wireless power transfer can be evaluated.

$$X_1 = j\omega(L_1 - M) \tag{3}$$

$$X_2 = j\omega(L_2 - M) \tag{4}$$

$$X_M = j\omega M \tag{5}$$

$$X_{C_2} = \frac{1}{j\omega C_2} \tag{6}$$

Equations (7) and (8) give the calculated values for Thevenin voltage U_T and impedance Z_T, for system operating at resonant frequency $\omega = 1/\sqrt{L_2 C_2}$. Fig. 3 shows the wireless power transfer system with equivalent Thevenin power supply.

$$U_T = U_S \frac{M}{C_2} \cdot \frac{R_2(R_S + R_1) + \omega^2 M^2 - j\omega L_1 R_2}{\left[R_2(R_S + R_1) + \omega^2 M^2\right]^2 + (\omega L_1 R_2)^2} \tag{7}$$

$$Z_T = \omega^2 L_2^2 \frac{\omega^2\left[L_1^2 R_2 + M^2(R_S + R_1)\right] + R_2(R_S + R_1)^2}{\left[R_2(R_S + R_1) + \omega^2 M^2\right]^2 + (\omega L_1 R_2)^2} + j\omega L_2 \left[\frac{\omega^4 M^2 L_1 L_2}{\left[R_2(R_S + R_1) + \omega^2 M^2\right]^2 + (\omega L_1 R_2)^2} - 1\right] \tag{8}$$

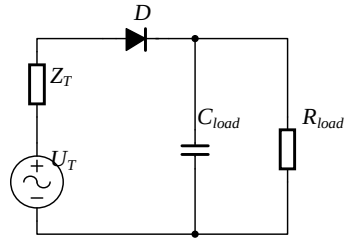

Figure 3. Wireless power transfer system with equivalent Thevenin power supply

Figure 4. shows the Thevenin voltage and impedance for different values of mutual inductance *M*, which derives from physical placement of the coupled coils L_1 and L_2. Since the distance between coupled coils and their three-axial alignment are not constant, U_T and Z_T vary in a wide range of values.

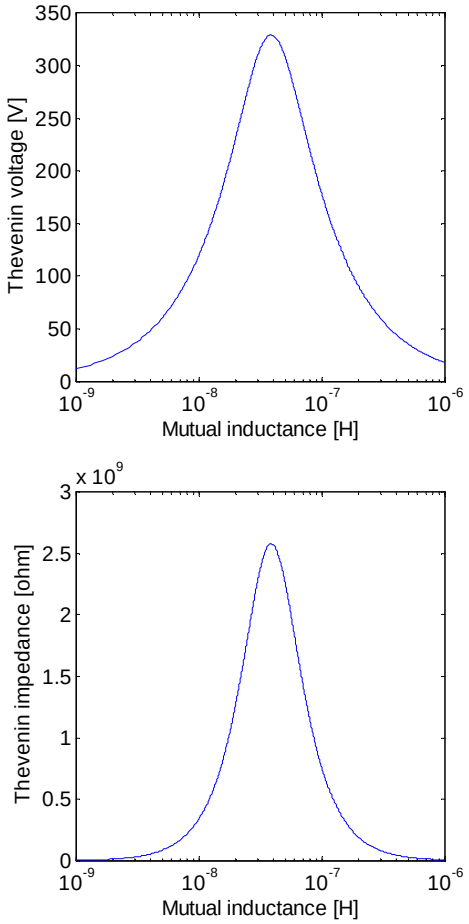

Figure 4. Thevenin voltage and impedance for different M values

Analytical results shown in Figure 4. correspond to coils with resistance $R_1 = R_2 = 0.1\ \Omega$. With a higher resistive part of the coupled coils, that is, with lower Q factor, a maximal achievable voltage at the secondary side lowers.

From Fig. 4. can be seen that maximal voltage is achieved for $M = 5 \cdot 10^{-7}$ H. Therefore, the Fig. 5 gives the Thevenin voltage values for various combination of R_1 and R_2, with $M = 5 \cdot 10^{-7}$ H.

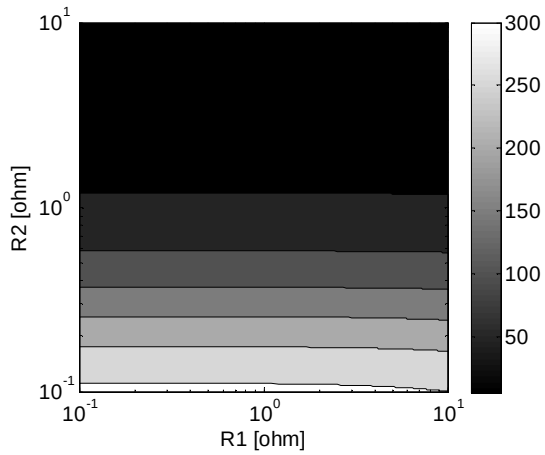

Figure 5. Impact of Q factor (R_1 and R_2 resistance) of coupled coils L_1 and L_2 on Thevenin voltage value

It can be seen that the Q factor of the secondary side has significant impact on power transfer performance, therefore the coil design with highest possible Q will be the main focus of many design requirements. It has to be about the same size as the cell phone because the transmitting and the receiving coil should be ideally the same size. It has to have the highest possible Q, and must operate at the highest frequency without transmitting radio waves (RF). That is possible if the wavelength is small enough with respect to the dimensions of the coil itself. This is satisfied for the mobile phone sized coil and frequencies in high frequency region (HF) which spans from about 3 to 30 MHz.

A frequency spectrum in HF region that is not occupied must be used. According to [8] for frequency spectrum in Croatia there is a lot of choices of unused frequency bands. The best spectrum region would be the one with the widest spectrum of unused frequencies. With that in mind one choice is the obvious and that is frequency region from 15.8 to 17.48 MHz which is 1.68 MHz wide. Since we don't want to interfere with occupied spectrums we will chose the middle of our chosen spectrum which is 16.64 MHz. This is the target frequency of the presented system.

Using frequency in HF region has its downsides. In the MHz range skin effect can have influence in the final charger performance.

Skin effect is an effect where current is forced to the outer edges of a conductor. The effect is more evident as the frequency goes up. According to (9) the skin depth at 16 MHz is around $1.631*10^{-5}$m [4]. Since the coils and conductors will be made on an printed circuit board (PCB) this will not have a significant impact, because there will still be 93.2 % of the conductor used, since the copper thickness on PCB is 0.035 mm.

$$\partial = \sqrt{\frac{\rho}{\pi f \mu}} \tag{9}$$

Where ∂ is the skin depth of the used conductor with conductivity ρ and magnetic permeability μ, at the given frequency f.

III. CIRCUIT

With the theory explained, in this section the practical design is described. First the design requirements. Transmitter needs to be practical and as small as possible which means it should be built as a charging pad not much larger than the phone itself. Receiver should be small to fit on or in the phone and simple to manufacture. It has been concluded that both transmitting and receiving coil need to be with the highest quality factor achievable on the PCB. The coils should not be considerably larger than the cell phone because the secondary coil should be able to enclose the open surface area in the middle of the primary coil. The reason for a spiral planar coils usage is their convenience for the flat pad charger, and they can also be easily built in the cell phone itself.

Starting at the transmitter the easiest way is to make it from single piece of PCB and as simple and as reliable as can be done. What is needed is an oscillator with stable frequency, power amplifier and a transmitting coil that resonates.

In Fig. 6. the schematics for the transmitter can be seen. It consists of an oscillator made from 16 MHz crystal oscillator and an inverter.

Signal is then amplified with the five remaining inverters in a 14 pin inverter chip. Next, there is a low pass filter designed to filter out crystal oscillator harmonics and to limit the current drawn from the oscillator. From there we have a power amplifier made from two transistors. They are connected in a Darlington configuration for power amplification. The transmitter coil and a variable capacitor are connected for parallel resonance. In that configuration the minimum current is drawn when resonance is achieved. This is a good way for controlling the current and the transmitted power. There is also a current limiting resistor R_6 for protection. Since parallel resonance is used, the voltage on the transmitting coil is double of the input voltage of the wireless charger.

The PCB is designed so that both parallel and serial resonances can be achieved. The same thing is made for the receiver. Testing has shown that using parallel resonances for both the transmitter and receiver works fine and does not deliver too much power to the cell phone.

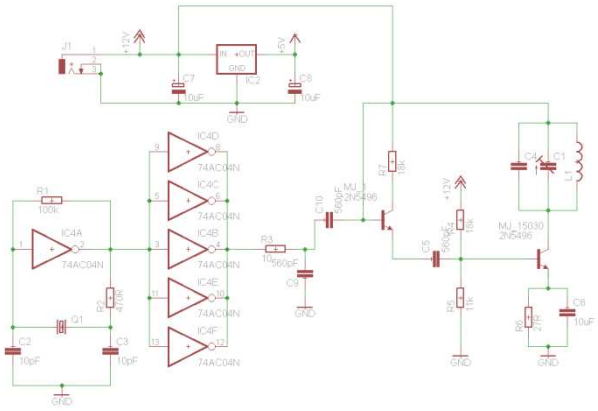

Figure 6. Final schematics for the transmitter

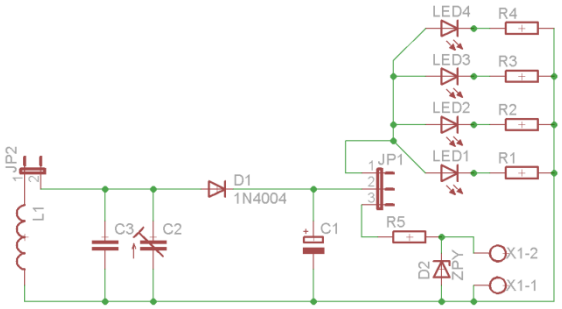

Figure 7. Receiver schematics

The receiver as shown in Fig. 7 is made from LC oscillator (for both the parallel and series resonance), one diode rectifier, filtering capacitor, and a zener diode. There are also four white LED diodes for demonstration purposes. Using jumper JP1 from Fig. 7 we can choose to light up the LED's or to charge a phone. Jumper JP2 is used to choose from series or parallel resonance mode.

Design of the schematics and the PCB was done using Cadsoft Eagle Professional 5.7.0. The final product is shown in Fig. 8.

Figure 8. Final wireless cell phone charger

IV. MEASUREMENTS

The most important measurements are power consumption, power transfer efficiency, wave forms and spectrum analysis.

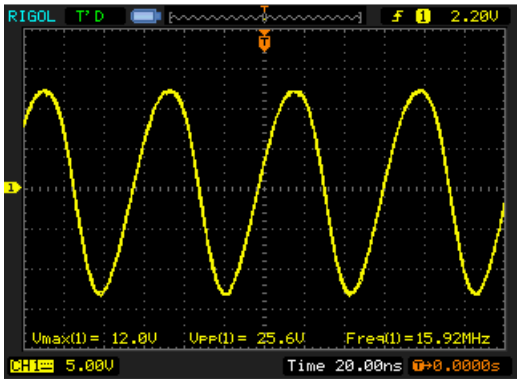

Figure 9. Voltage waveform on the receiver coil

As can be seen in Fig. 9 on the receiver we get 25.6 V peak to peak sinusoidal waveform. Since only 5 V is needed, this seems too much, but this voltage will drop under load. How much it will drop depends on transmitting coil inductance and quality factor. In our case it drops to about 12V, and the rest is removed by zener diode. The final charger is tuned so there is not a lot of excess voltage. Using series resonance on the receiving coil voltage would drop and the current would rise. Since we are using parallel LC receiving setup exact resonance does not have to be achieved and tuning the circuit becomes easier. Also the detuning over time by aging components and by accident has less of an effect on the chargers performance.

Next set of measurements are power transfer efficiency tests. Maximum power drawn from the circuit was 100 mA at 5 V. This results in 0.5 W on the secondary while the primary was using 3.042 W. That means this charger is around 16.44 % efficient. Much higher efficiencies where achieved according to [2], but with such low power consumption in the first place this results are acceptable. With further tuning the efficiency could be raised.

Frequency spectrum that is being radiated can cause interferences with other nearby systems or with the phone itself. Crystal oscillators have high quality factor in respect with other oscillators such as phase shift oscillators. This means that their higher and lower harmonics have quite large amplitudes with comparison to their basic frequency. This is clearly shown in Fig. 10.

Having filters to prevent higher harmonics from being amplified or transmitted becomes very important. This prototype does transmit some signals beyond HF region, but these harmonics can be easily filtered.

Cell phones have couple of antennas built in them, and every conductor inside them can pick up noise from the wireless charger. It is also important to check if the cell phone can establish a connection with the base station and send or receive messages. It also must be checked if other function of the phone work. With presented design no problems were located and every tested function worked without any problems.

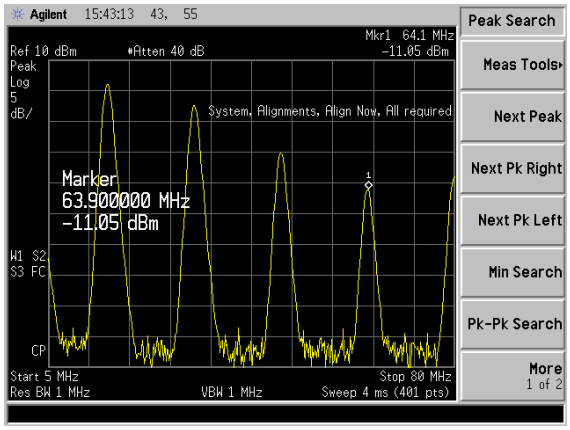

Figure 10. Frequency specter of the crystal oscillator

V. CONCLUSION

The presented concept of the wireless mobile phone charger has an operating distance up to 2.5 cm between charger and mobile phone. Power transfer of 0.5 W is accomplished, which is sufficient to charge a mobile phone. The charger design is simple enough and it does not interfere with the mobile phone functionality while the device is charging.

For the future work, the communication technology integration in the charger is needed. Bluetooth can provide the communication option to the charger that needs to have more functionality since it is practical only for a desktop use. Size of the transmitter and the fact that it still needs a regular power adapter make this charger unpractical if charging the phone is its only application.

Standardizing the chargers will not be enough for the future use. As the power demands grow every day electronics need to be as functional as possible and as energy efficient as we can make them. To keep the power consumption at its minimum and to keep the batteries from overcharging phones processor can be used to regulate the charging process (smart charging). With the integration of Bluetooth communication and implementation of smart charging, wireless charger has a chance to change the way we use our phones and to become a very useful tool.

Hardware realization of autonomous robot localization system

Brkić Miodrag*, Milan Lukić*, Jovan Bajić*,Bojan Dakić * and Milorad Vukadinović*
*University of Novi Sad/Faculty of Technical Sciences/Department of Power, Electronics and Communication Engineering/Novi Sad Serbia
brxnet@yahoo.com

Abstract - One of the most important problems in autonomous robot guidance is their localization, i.e. determining their physical location within their operating area. In this paper we describe hardwre realization of triangulation method for localization of wheeled autonomous robot that operates on flat rectangular surface. Triangulation is a method of calculating location of robot relative to 3 landmarks (beacons) located on fixed predetermined positions. This method usually needs measurement of distances between robot and beacons, to be able to calculate robot position. Different approach based on angle measurement is described in this paper, advantages of this method are discussed and details of hardware realization are explained. System is realized and tested, measurement results are given.

I. INTRODUCTION

For autonomous robots which must operate without human interfering it is of vital importance that robot has information about its position on the playing field available during the whole duration of the match. There area many systems used for robot positioning, depending of the type of the robot and location where it will be used indoors or outdoors, flat or uneven terrain, small or large moving space…

System in this paper is designed to be used in EUROBOT [1] competition, with mostly flat playing field of relative small dimensions (2x3m). Simple localization systems for this type of terrain uses infrared beacon which allows them to know their orientation on the field, but not exact location. More complex systems use ultrasonic measurements [2], but these systems are not useful in location with significant environmental noise. Camera systems with image processing [3] are most sophisticated, and can be used in robot navigation, since these systems can be developed to detect object on terrain. These type of systems suffer from problem of variations in environmental illumination, complex algorithms and quality hardware must be used to operate in these conditions.

There are numerous papers [4], [5] with robot localization system based on infrared beacons, but they are usually with emphasis on theoretical explanation of this type of systems and algorithms for their calculation, they don't present hardware realization of the system. In this paper, we first describe some of the existing and frequently used localization methods in EUROBOT competition, and then we describe our localization method based on angle measurement, with detailed hardware description. Similar system for robot localization is reported in [6]. This system uses additional lens and mirror for directing optical signal to the sensor. High quality mirrors reflected above 80% of the incident light but they are quite expensive. Same goes for good lens. Additionally, in order to achieve maximum efficiency of the beam directing, lenses and mirrors must be accurately adjusted. In this paper we propose another solution without the use of additional optics which allows greater range of the sensor. Our solution is based on rotary transformer which allows contactless transfer of supply voltage to the sensor, as well as transfer of signal from sensor.

The position is calculated by sensor measurements. Since the robot moves on the bounded flat surface, its position is fully defined by three coordinates (x, y). Coordinates x and y actually signify the position of robots central point in fixed coordinate system anchored to the playing field, and is the orientation, i.e. the angle between central axis of robot and x axis (Fig. 1).

II. LOCALIZATION METHODS

A. Odometry

Odometry [7] is a robot localization method based on usage of rotary encoders. The robot has two wheels which are constantly in the contact with the surface. These wheels are mechanically coupled with encoders. The number of the pulses produced by encoders depends on the number of turns, in other words the distance traversed by wheels. This is an incremental method, which takes into account the assumption that the robot trajectory consists of sequence of segments that are approximately straight. The data coming from encoders is processed periodically, with a period short enough that the assumption about the straightness of trajectory segments still holds (10 ms). If we assign the number of encoder increments read from respective encoders during nth period by LEFT and RIGHT, it is possible to calculate the growth for all three coordinates during given period.

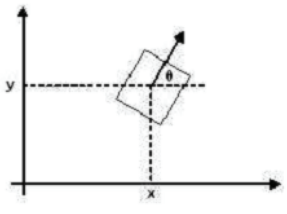

Figure 1. Position of robot in coordinate system

Basic flaw of this method is existence of systematic error which accumulates through time. The error appears due to slipping of wheels, the assumption of straightness of trajectory between two consecutive readings, numerical error of calculation, etc. It is possible to acquire information about robot position with acceptably small deviation with this method, but if robot slides laterally (in contact with opponent robot or some object) , system based on this method will not be able to correct error that will be produced on this situation, or even to be aware that error has happened.

B. Triangulation Based On Distance Measurement

Triangulation is well known and frequently used localization method. The position of robot is determined by measuring distances between the robot and three fixed points on known positions. For this purpose, we use three beacon positions on the edge of the field, as defined in competition rules. In Fig. 2, these positions are designated by B_1, B_2 and B_3. One of the ways to measure distances L_1, L_2 and L_3 between robot and beacons is to put an ultrasonic transmitter in each beacon and ultrasonic receiver in robot. By measuring time between the moment of issuing the command and reception of ultrasonic signal, it is possible to calculate distances, knowing the speed of sound.

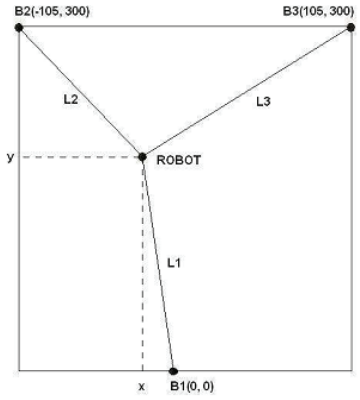

Figure 2. Triangulation based on distance measurement

Now that we have measured distances L_1, L_2 and L_3, it is possible to calculate position of robot. The coordinate system is perpendicular to the playing field, with origin in B1. The unit of measure is centimeter, so the positions of the beacons are B2 (-105, 300) and B3(105, 300). By applying basic trigonometric laws, we get the following equations for robot position:

$$x = \frac{L_2^2 - L_3^2}{420}$$

$$y = \sqrt{L_1^2 - x^2}$$

The advantage of this method is that it doesn't accumulate error. When it comes to realization, the biggest problem is inadequacy of measuring methods.

The ultrasonic receivers are too sensitive to environment sounds, which leads to false distance measurement in environment that is not quiet. More sophisticated methods of distance measurement such as laser measuring sensor can be used, but this type of equipment is very expensive. It is also important to mention that this method cannot provide the information about robot orientation, so it would be necessary to use some other system do measure it (i.e. electronic compass).

C. Triangulation Based On Angle Measurement

Our approach to localization problem is based on angle measurement. Like in previous section, we use three beacons again, but this time we use coded infrared beacons. All of the beacons continuously and simultaneously transmit modulated infrared light signals with different codes, by which a receiver unit on the robot can distinguish them. The receiver sensor is in the end of the narrow cylinder which is mounted on the rotating platform. The cylinder has a narrow aperture in order to enhance directivity; the receiver is able to receive and decode the signal only when it is watching directly towards the transmitter. The mechanism that turns the receiver around contains a sensor that provides the information about its orientation (i.e. rotary encoder). This way, by turning the receiver for a full circle the robot is able to register in which positions it sees all of the 3 beacons, in other words to measure angles between these positions. The situation is shown in Fig. 3.

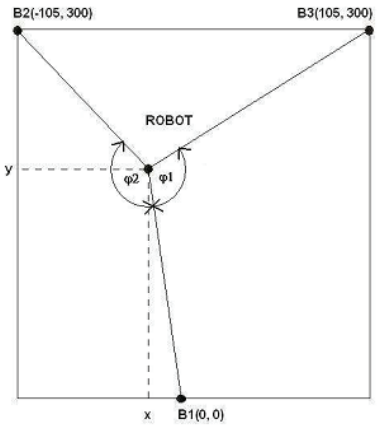

Figure 3. Triangulation based on angle measurement

If we designate the central point of robot by R, by measurement we acquire angles $\varphi 1 = < B1RB3$ and $\varphi 2 = < B1RB2$, which are the input parameters for the equations that are used for determining the position

We get the equations for calculating the position by using the following idea. Geometrical place of points R such that angle $< B1RB3 = \varphi 1$ is a circle with center in C1 (x1, y1), constructed above the chord B1B3, with inscribed angle $\varphi 1$. That property comes from the theorem that all of the inscribed angles over the same chord (in this case B1B3) are equal. The same way, we can construct a circumscribed circle with center in C2(x2, y2), constructed above the chord B1B2, with inscribed angle $\varphi 2$. These two circles intersect in two points, one of which is B1, and the other is R. So, the first step is to determine positions of C1 and C2 by applying laws of

trigonometry and analytical geometry. It can be shown that:

$$r_1 = \frac{\sqrt{\frac{L_1^2}{4} + L_2^2}}{2\sin\varphi_1}$$

$$x_1 = \frac{L_1}{4} - \frac{L_2}{2} ctg\varphi_2$$

$$y_1 = \frac{L_2}{2} - \frac{L_1}{4} ctg\varphi_1$$

Lengths of sides of playing field are L1 and L2, r1 and r2 are radiuses of circumscribed circles. In equations for r2,x2 and y2 φ2 is used instead of φ1.

After we have calculated coordinates of centers of both circles, we determine robot coordinates by solving the system of circle equations:

$$(x - x_1)^2 + (y - y_1)^2 = r_1^2$$

$$(x - x_2)^2 + (y - y_2)^2 = r_2^2$$

By solving the system, we get final equations for robot coordinates:

$$x = 2\frac{(x_1y_2 - x_2y_1)(y_2 - y_1)}{(y_2 - y_1)^2 + (x_1 - x_2)^2}$$

$$y = 2\frac{(x_1y_2 - x_2y_1)(x_1 - x_2)}{(y_2 - y_1)^2 + (x_1 - x_2)^2}$$

III. SYSTEM REALISATION

Since maximum speed of the robot can be up to 1m/sec or even more in short period of time, to achieve constant monitoring of position of robot system localization system has to calculate its position adequately fast. For margin of error of 10 cm, which is usually acceptable, system must be able to give 10 measurements in one second. To achieve this speed, we used brushless DC motor from VCR as rotating platform. This motor is integrated with rotary transformer which allows contactless transfer of supply voltage to the sensor, as well as transfer of signal from sensor to the microcontroller that is used for its decoding, and later for calculating the position.

Since motor needs 100 ms to rotate full circle, receiver is "seeing" the transmitters for the time that motor need to turn around 1 ° ,or 100ms/360=270us. Each transmitter are sending unique code continuously, and to distinguish them code should be at least 10bit-s long, which leads to 27us for one bit. Duration of each bit is 10 periods of carrier (Fig. 4), so one period should be minimum 2.7us. To receive this signals we use TSOP7000 infrared (IR) receiver [8], which receives the signal modulated on 455 kHz (signal period of 2.2 us).

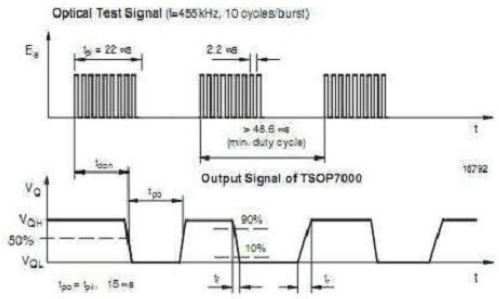

Figure 4. Coded beacon signal and output signal from TSOP7000

Transmitters are realizes with low-cost microcontrollers which generates adequate signal for IR diodes. Since IR diodes which we use have radiation angle of 20°, an array of this diodes is used, to send IR signal on whole playfield.

Communication between transmitters (beacons) and the receiver is done via standard UART (Universal asynchronous receiver/transmitter) protocol which greatly simplifies the decoding of the corresponding beacons. Each beacon continuously transmits a unique code via UART protocol.

Functional diagram of receiver system is given on Fig. 5.

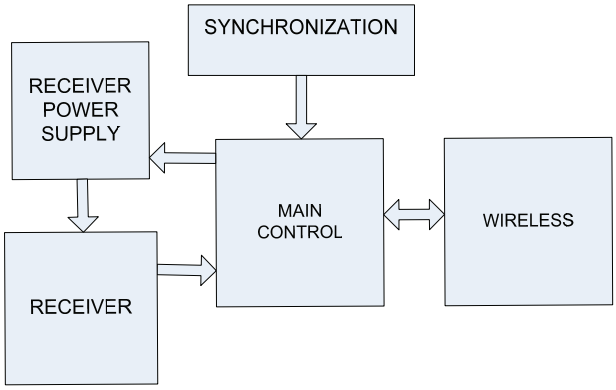

Figure 5. Functional diagram of receiver system

A. *Power supply for receiver circuit*

Since IR receiver is on rotating part of the motor, and rest of the electronic are fixes, no wire connection is possible, so rotary transformer is used to supply power. To achieve that main controller sends square signals of around 250 kHz to integrated H-bridge, which drives primary of transformer. On secondary of transformer simple diode circuit is used to obtain DC voltage.

B. *IR receiver circuit*

Acceptance angle of the infrared receiver TSOP7000 is around 90°. To increase the accuracy of the robot localization, acceptance angle must be reduced. Otherwise the error in determining the angle between the beacons can be very large, and therefore the position of robots would be misleading. In order to reduce acceptance angle, sensor (TSOP7000) is packaged in a casing with two parallel slits (Fig. 6). In this way light can reach sensor

only through the slits and acceptance angle of the receiver is reduce from 90 ^{O} (Fig. 6 b) to about 1 ^{O} (Fig. 6 c).

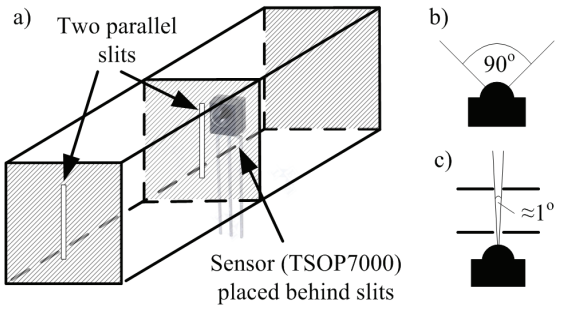

Figure 6. Sensor packaged in a casing with two parallel slits

Output of IR receiver TSOP7000 is in form of TTL logic signals. Output is connected to buffer realized with operational amplifier which also drives second pair of transformer coils. On secondary coil this signal is attenuated and mixed with signals from supply coils, but since frequency of useful signals is around 30 kHz, it is possible to extract them with active four-pole low pass filter. Next stages are amplifier and comparator which regenerates signal to TTL levels. Signals are then send to microcontroller.

C. *Synchronization circuit*

Although brushless motor have constant speed during one rotation, it changes with time due to decrease of battery supply of whole system. To know the time motor needs to make one rotation, we use hall sensors in combination with small permanent magnet connected to rotary part of the motor. Once per rotation hall sensor gives rising signal, but duration and amplitude of this signal varies with speed of the motor, and since there is low frequency hum from surrounding electronics, additional processing is required before it can be send to microcontroller. High pass filter eliminates noise, and voltage comparator sets level of the signal to TTL logic.

D. *Wireless communication*

This localization system is suitable for detecting the position of opponent robot, because it is allowed to put a beacon system on top of it. Then, the system uses wireless link to inform our robot about opponent position, which is very important for collision avoidance (as it is strictly forbidden by rules).

XBee module is used for wireless communication. This module has range of around 10 meters, and is able to send data on 115200 bauds, which is more than needed for our application. It is connected to serial port of microcontroller. Besides data transfer, Xbee module enables wireless control of power on and off localization system, which can significantly expand battery life.

E. *Main control circuit*

Control circuits consist of microcontroller and its peripherals. Microcontroller receives data from receiver, computes triangulation algorithms and sends position data over wireless module. It also controls peripheral circuits and motor speed.

IV. EXPERIMENTAL RESULTS

In Fig. 7 photograph of receiver of the implemented system for robot localization is presented.

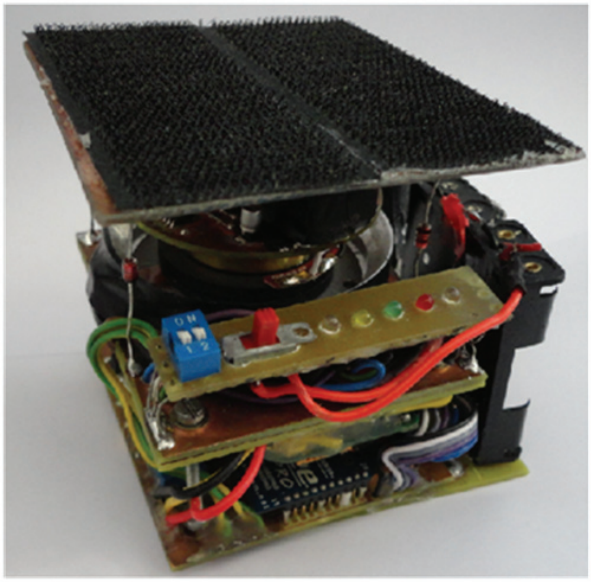

Figure 7. Photograph of the receiver for robot localization

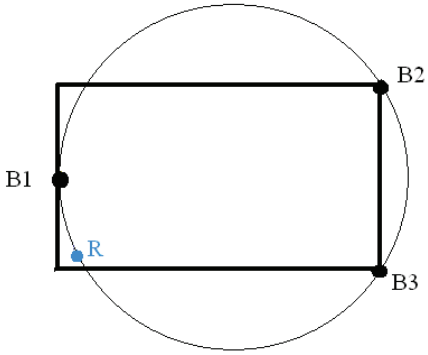

Figure 8. Robot and all beacons lies on the came circle

This system was realized and tested on the playing field for EUROBOT competition. Most precise measurements were on the center of the field, and highest errors were measured when robot was close to the parts of the fields where circle on (Fig 8.) intersect with the field. This is the extreme case when the robot and all beacons lie on the came circle, and the intersection point is not unique so position of the robot is not attainable, as it was explained in paper [4]. In this situations system detects that measured position is wrong, and that measurement is omitted. This is the reason that last measurement on Fig. 9 is omitted, and why is measurement on bottom right position so incorrect, with error above 30cm.

On Fig.9 measurement results (for the speed of 10 revolutions per second) on whole table are presented, usual error for both x and y coordinate was up to 5 cm, except on one position where this error was 10 cm. Measurement results from positions close to circle from Fig. 8 were useless. When rotation was slower, more

precise results were achieved, typical error was up to 2cm for speed of 2 revolution per second.

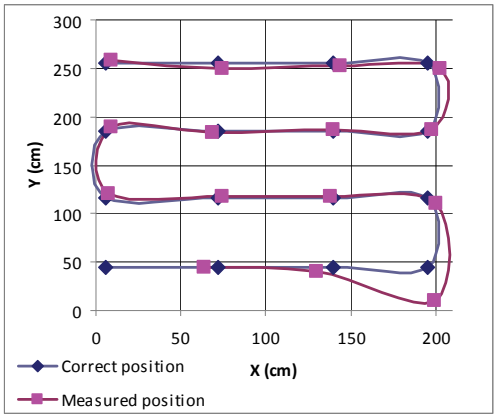

Figure 9. Measurement results for speed of 10 revolutions per second

In addition, measurement up to 5 meters between receiver and transmitter were made, system was able to detect transmitted code on every measurement.

V. CONCLUSION

In this paper we described details of realization of a sensor system for determining position of an autonomous robot. The system has been developed and successfully used in EUROBOT competition in 2011. This system is relatively cheap, especially compared to a laser triangulation system. Besides, it is much more reliable than an ultrasonic system. Still, it is prone to error of angle measurement, mostly because of different periods of time needed to detect transmitted code. Still, such system is suitable for detecting the position of opponent robot, because achieved precision is adequate, and it is allowed to put a beacon system on top of it.

This system can be easily adapted to be used in other applications, by readjusting beacons and location constants. It can be also used on larger areas, distances up to 5 meters were successfully tested, and even larger distances can be obtained with increase of number of transmitter IR diodes.

Abstract - In this paper, the developed digital excitation control system was evaluated to get the strength of operating situations in the small power plant. Recently, most automatic voltage control systems for big power plants employ a quick response and stationary excitation technology. But cost of older excitation systems has been prohibitive for redundancy. And they add much complexity to the system relative to wiring and interconnection. To solve these problems, the new redundancy digital excitation control system was developed. This system ensures adequate steady-state, dynamic reactive reserves, and zero tolerance. In addition, it provides protective features for the generator such as over flux limiting and field current limiting. Finally, the performance of this digital excitation control system was verified in a gas turbine of a coal-fired plant.

I. INTRODUCTION

Recently, most companies which have operated a small power plant require generators to be operated stably at all times, to ensure adequate steady-state and dynamic reactive reserves. [2,3] Generator owners have zero tolerance for unit trips. Therefore an automatic voltage regulator (AVR) has been used to provide voltage control of the generator output by controlling the excitation current. [1,4] The AVR plays a significant role in excitation control systems. It must provide a response which has an acceptable dead time, rise time and settling time. It should be bump-less transfer from manual mode to automatic mode and vice versa.

At the present time, most excitation control systems have been designed as complete specification for large turbine generators. [5,6] In older excitation systems, cost would have been prohibitive for redundancy, while adding much complexity to the system relative to wiring and interconnection. So, most power system companies can't install the excitation control system. Therefore, the development of cost effective excitation control system is required to provide wide range adjustment of all control and protection parameters.

In recent years as digital processors have become very advanced, it is not uncommon for any machine to have either complete redundancy or some form of it. [7,8] Digital control systems are also more flexible in this respect than analog electronic control systems. Moreover, the control parameters can easily be defined and adjusted. The operator can adjust operating parameters such as the voltage or MVAR set point. This paper describes the cost-effective redundant digital excitation control system.

II. IMPLEMENTAION OF PROTOTYPE

A. Hardware Design

In this paper, the cost effective digital excitation control system as called KDR-1200D was developed using a high performance microprocessor for small power plants. This KDR-1200D consists of a main controller and signal interface modules. The main controller based on 32 bit DSP is a core device of the digital excitation control system. This main controller plays a significant role in providing fast and accurate voltage control to the power system using results from operating analog signals such as voltage, current, etc. The SIM (Signal Interface Module) and ETP (External Terminal Panel) are I/O signal interface modules. They were designed to be simply detachable with the KDR-1200D.

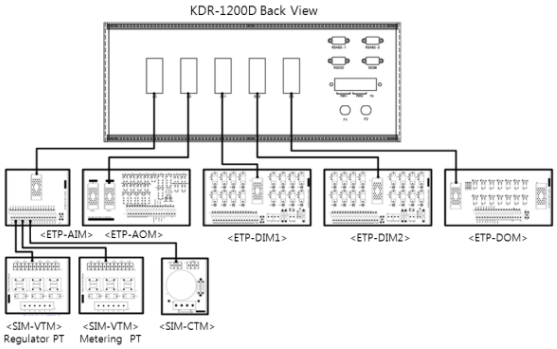

Figure 1. Units MComposition of Redundant Digital Excitation Control System (Main Controller, Signal Interface Module, External Terminal Panel)

- SIM (Signal Interface Module)
  - Voltage Transformer Module (Regulator PT, Metering PT)
  - Current Transformer Module
- ETP (External Terminal Panel)
  - Analog Input Module.
  - Analog Output Module.
  - Digital Input Module.
  - Digital Output Module.

- Scan Power Check Module.

B. Software Design

The digital excitation controller is primarily required to provide voltage control of the generator output by controlling the excitation current. The controller must provide a prompt and exact response which has an acceptable dead time, rise time and settling time. Therefore the proposed digital excitation controller was developed using quick-response and static excitation method to be economical redundancy configuration.

First, the digital excitation controller supports two operating modes which are Automatic mode and Manual mode to control voltage of the generator output. The Automatic Mode can be defined as automatic voltage regulator (AVR) which controls output voltage of the generator. The Manual mode can be defined as field current regulator (FCR) which controls field current. The operating mode control function was built into the microprocessor based digital excitation control system. In this controller, Automatic mode and Manual mode were embedded in the same hardware and software. See Figure 2.

The main controller has the high performance DSP and RTOS(Real Time Operating System) to reduce operating load and of a controller. Because the controller must calculate an effective voltage (V_{trms}), an effective current (I_{trms}), frequency, electricity(P), caloric value(Q) using input values such as PT, CT, field voltage, filed current at sampling rates of 180Hz.

The application software uses Preemption Based Multitasking function that RTOS provides. This function divides into some independent or dependent tasks through binding all tasks related to one another. In addition, the software carries out a role after pre-occupying CPU according to each given priority. In other words, some tasks periodically operate, others only operate as an environment changes. Although separate tasks have each particular role, they make close relationships through sharing information by special functions such as sharing memory, mutual task communication. Basic tasks of our digital excitation controller are as follows.

- Initialization Task
- Control Task
- Protection Task
- Communication Task

These tasks are operating in a different frequency as well as individually carrying out their functions. The control part is divided into two parts, automatic and manual. The automatic part which includes AVR(Auto Voltage Regulator), UEL(Under Excitation Limit) is controlled at 180Hz, while manual part which includes FCR(Field Current Regulator), OEL(Over Excitation Limit) is controlled at 360Hz.

III. REDUNDNCY

Figure 2 illustrates the redundant control block diagram of Master/Backup controllers. Master and Backup controllers are embedded in the same hardware. Specially, the digital excitation control system can choose an operating mode using a particular switch. Therefore the main controller can be set as Master or Backup controller. In this paper, two main controllers are used for redundancy. One is Master controller, another is Backup controller. Two controllers are connected with a Relay Logic board. The board detects faults of the digital excitation systems and produces a transfer signal.

Each controller has a Watch Dog Timer (WDT) which periodically generates a pulse signal to detect system faults. The WDT can detect any problems on one between DSP and FPGA. The principal signals use RS-422 protocol to communicate between the digital excitation controllers. The Backup controller was designed to follow the principal signals of the Master controller. If Backup controller is operating as a Master controller due to a Master controller's faults, the repaired Master controller follows the principal signals of the Backup controller. The principal signals include control valuables such as integration value to follow output values of other controller. Therefore Master/Backup controllers are complementary according to a transfer signal. It is possible to repair the faulted controller without operation stop of a generator by the redundancy of digital excitation control controllers.

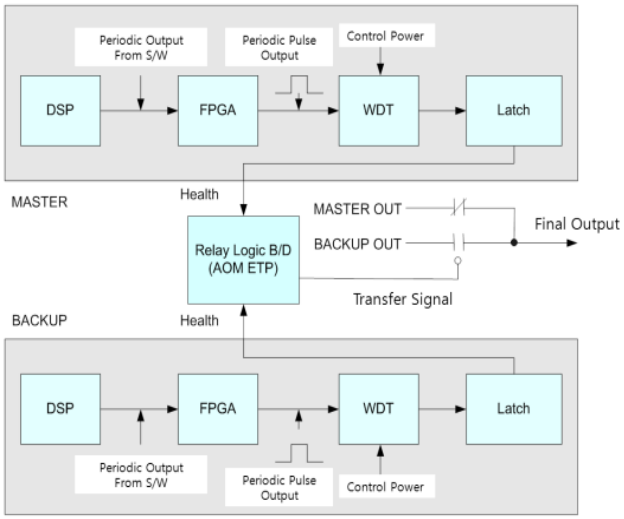

Figure 2. Redundant Control Block

Figure 3 describes change strategy of operating mode for Master/Backup controller when any controller failed. When the digital excitation control system was initially driven, Master and Backup controllers operate independently in a first Auto mode. Specially, each controller follows other's principal signals to reduce transient state characteristics in a redundancy transfer switch. If Master controller failed, the Master controller disconnects and Backup controller plays as a Master controller. If Backup controller failed by potential transformer faults during operating as a Master controller, the operating mode of Backup controller changes from Auto mode to Manual mode. Consequently, If a malfunction was detected, the system was transferred to Manual mode to keep the generator up and running. So it allows a repair or replacement while operating on-line of the manual voltage regulator.

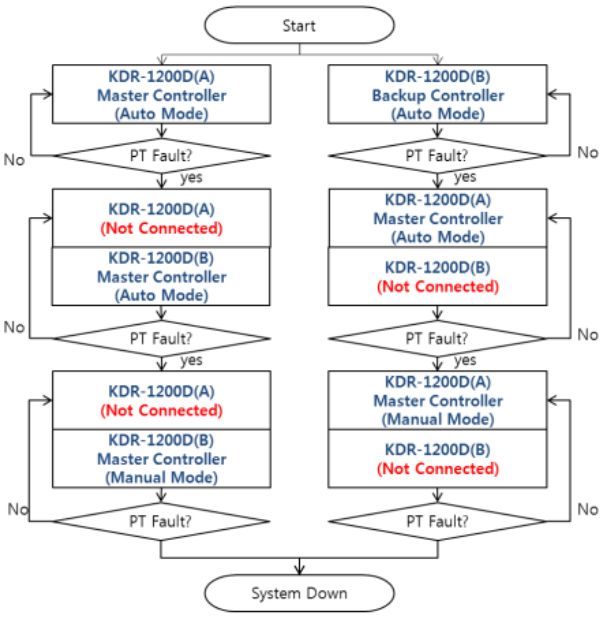

Figure 3. Flow Chart of Master / Backup Controller Operating Mode

IV. PROTECTIONS

This KDR-1200D autonomously provides comprehensive functions to protect rectifiers. The following is a list of the protective functions, along with a brief description of their purpose and the system parameters they monitor.[9,10,11]

- Volts/Hertz Protection (HXP)
- Over Excitation Protection (OEP)
- Generator over Voltage Protection (OVP)
- PT Failure Detection

The Volts/Hertz Protection (HXP) is similar to the Volts/Hertz Limiter (HXL) but instead will apply a trip or alarm signal. This function typically operates on an inverse timing curve that is meant to model heating characteristics of a generator or step-up transformer during over excitation.

The Over Excitation Protection is similar to the Over Excitation Limiter (OEL) but instead will apply a trip or alarm signal once the field current or voltage is above a set point, typically after a fixed or inverse time delay above the OEL.

The Generator Overvoltage Protection measures generator output voltage and initiates an alarm or trip signal when over a specified set point, typically with some settable time delay that is coordinated with the Over Voltage Limiter (OVL).

The generator terminal voltage was typically measured through some transducer. The PT Failure Detection initiates an alarm or trip when below a set point or, in some cases, if an unbalanced condition exists, typically with some settable time delay. In addition, this function provides transfer to redundant potential transformer. When a loss of voltage sensing event takes place, the voltage sensing inputs are switched to use redundant PTs.

V. PEFORMANCE TEST OF GAS TURBINE

This digital excitation control system was evaluated in a gas turbine of a coal-fired plant. Table I describes the generator specification of a relevant coal-fired plant. The following is a list of the major items in field test. This field test was only performed in off line conditions (No Load conditions).

- Terminal Voltage Build-up in Auto (AVR) Mode
- Terminal Voltage Build-up in Manual (FCR) Mode

TABLE I. GENERATOR SPECIFICATION OF COAL-FIRED PLANT

Rated Capacity	112,800 [KVA]
Rated Voltage and Frequency	13,800 [V], 60[Hz]
Field Voltage and Current	300 [V], 900 [A]
Power Factor	0.9

A. Auto Mode Terminal Voltage Build-up Waveform (No-Load Condition)

In off-line condition (no load condition), the build-up waveform was measured to check the terminal voltage change trends in Auto mode. Table II and III summarize the performance test results. In this test, the generator's operation data such as terminal voltage, frequency, field voltage, and field current were measured. The generator's terminal voltage was generated from the Soft-Start by a field breaker over 95 % to rated speed of a gas turbine. In other words, the rated voltage rates by Auto mode Soft-Start were approximately 1.0 [PU]. Figure 4 shows the terminal voltage build-up waveform on Auto mode in off-line condition. The terminal voltage build-up waveform describes that the digital excitation control system was little bit stressed with few overshoot (less 1%) by Soft-Start. But the terminal voltage reached the steady-state within hundreds msec. The overshoot will be eliminated by tuning PI gain using trial-error method.

TABLE II. PERFORMANCE TEST RESULTS IN AUTO MODE

VI. CONLUSION

In this paper, the developed digital excitation control system was evaluated to get the strength of operating situations in the small power plant. The results of the performance test show that the digital excitation control system is being used to fulfill the requirements of an existing analog excitation control system. Its malfunction rates have decreased by noise reduction according to the digitalization.

In addition, the digital excitation control system provides more precision and exact protection as well as a limiter function. The redundant configurations for excitation control system was greatly improved compared to an existing analog excitation control system through the terminal voltage or field current monitoring in realtime. Consequently, our digital excitation control system offers a full range of reliable excitation systems. It improves the generator excitation control's effectiveness and deliver the performance, operability, and availability needed in the small power plant.

Abstract - A fully integrated multicolor photoreceiver is presented, which combines a triple junction photodetector, three transimpedance amplifiers and three output drivers in a single chip. Gain and offset can be adjusted individually for each path. The fiber (glass fiber or POF) can be directly coupled onto the light sensitive area of the integrated receiver. The usable wavelength range is from 400 nm to 900 nm. The triple junction photodetector is designed based on the effect that light with longer wavelength can penetrate deeper into silicon than light with shorter wavelength. The three vertically stacked photodiodes can accurately and simultaneously convert light with different colors into different currents. The single chip photoreceiver is fabricated in standard 0.6 µm CMOS technology using an epi-wafer without any process modifications. Thus it can be realized cheap and with minimal packaging effort. In addition, the presented device can pave the way for a single visible WDM receiver – a solution optimal for high speed POF transmission systems. Based on the simulation results, we find that the designed photoreceiver can meet requirements of both color detections and a relatively high transmission rate up to 200 Mbps per color.

I. INTRODUCTION

The demand for low cost and high reliable photoreceivers increased largely during recent years because of the huge demand for optical data communication. These photoreceivers can be applied in many different areas, such as data communication in local area networks, fiber to the home (FTTH), in house communication like SOHO (Small Office, Home Office) networks, optical storage systems like DVD (Digital-Versatile-Disk) and so on [1].

On one hand, to reduce the cost of the photoreceiver, we can combine the photodiode together with the electrical receiver on a SOC (System On Chip), which is called OEIC (Optoelectronic Integrated Circuit). Such a technology can help, on one hand to increase the bandwidth (by reducing the parasitic) and on the other hand to reduce the chip area (by using less bond pads), which leads to reduced total costs of the packaged receiver.

In recent years many studies focusing on OEIC have been done. At first, a 2.5 Gbps silicon receiver OEIC including a PIN photodiode of 300 µm diameter was described [2]. Then, an 11 Gbps optical receiver integrated with a 50 µm diameter PIN photodiode was presented. This photoreceiver was fabricated in a technology with process modifications to achieve a high data rata, as a result, the cost of the chip increased [3].

After that, based on the basic concept of OEICs, some massively parallel optical receivers were presented [1], [4], which integrated at least three photodiodes with receivers into a single chip. Compared to designs with external photodetectors beside the amplifier IC, all of these integrated optical receivers can reduce the area of the whole system, which helps to reduce the cost of the devices. However, since most of these receivers use a PIN photodiode, certain modifications in the technology are necessary. In addition, all these photodiodes are biased by a very large reverse voltage such as 17 V, so it is necessary to supply this voltage externally. As a result, additional pads are necessary, which will also increase the chip area. Furthermore, all of these optical receivers are designed to detect light with only one distinct wavelength; therefore, they can not be used for wavelength division multiplexing (WDM) data communication.

On the other hand, many designs focusing on color detection have been realized. First, buried and triple p-n junction photodiodes were developed and applied for color sensors or color detectors[5], [6], [7], [8]. Secondly certain color filters were added to cover devices to select different colors (or wavelengths). Unfortunately, these additional filters increase the complexity of the chip production and often also the necessary silicon area (side by side layout) which increases the costs of the product.

Recently a filter-less multicolor photodiode was investigated to detect different wavelengths of light in a color sensor [9], [10]. The design of this novel color detector is based on the effect that light with longer wavelengths can penetrate deeper into silicon than light with shorter wavelength. Three vertically stacked pn junctions form the multicolor photodiode, which could overcome some drawbacks of conventional photodiodes with additional filters. However, up to now this kind of photodetector was only used for color sensors and continuous wave (CW) light applications. Therefore, we investigate how these novel photodiodes can be applied to modulated light in communication systems.

This paper reports a fully integrated multicolor photoreceiver, which integrates three vertically stacked photodiodes together with three transimpedance amplifiers and three output drivers into a single chip. Since the modulated light from optical fiber can directly illuminate the light sensitive area, this kind of photoreceiver can detect three different wavelengths of light simultaneously and accurately without any additional filters. Consequently the process complexity and also the size of the chip are reduced as well as the total cost of the whole device. This multicolor photoreceiver is fabricated in a standard 0.6 µm CMOS technology using an epi-wafer without any process modification.

II. PRINCIPLE OF THE MULTICOLOR PHOTORECEIVER

A. Overview of the whole chip

In this section we will describe the principle of the multicolor photoreceiver. The block diagram of the whole chip is shown in Fig. 1.

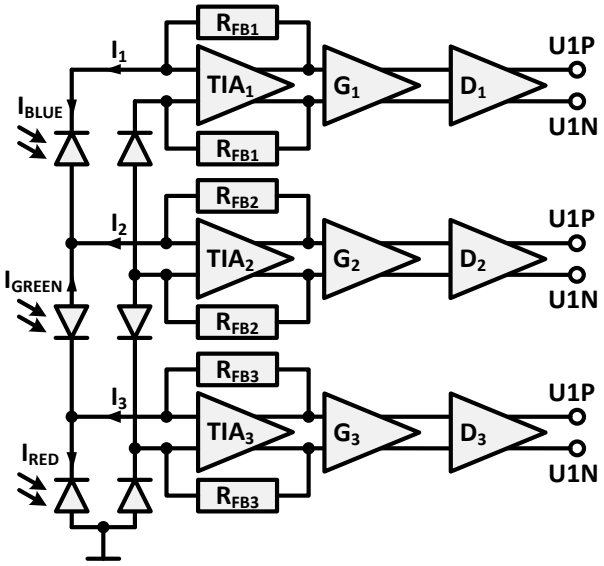

Figure 1. Overview of the whole chip

The photoreceiver works as follows: the modulated light coming from the optical fiber directly illuminates the light sensitive area of the multicolor photodiode, which transfers the optical signal into electric signal.

A transimpedance amplifier after the photodiode is used to convert the photocurrent, delivered from the photodiode, into a proportional output voltage.

To get enough amplitude for signal processing at the output a gain stage amplifies the output signal of transimpedance amplifier.

Moreover, digital processing is necessary to separate the different multi-color signals. Therefore the output signal will be fed into ADCs and a 50 Ω line driver circuit is necessary. Furthermore, a full differential structure was used to improve the PSRR (Power Supply Rejection Ratio) and consequently a dummy photodiode was added.

In a short summary, the designed photoreceiver consists of a multicolor photodiode, a dummy multicolor photodiode, three transimpedance amplifiers, three limiting amplifiers and three drivers.

B. Structure of the Multicolor Photodiode

Based on the effect that light with different color can penetrate into different depth of silicon, we designed this fully integrated vertically triple-junction photodetectors. It can detect different colors of light in different locations of the silicon wafer simultaneously and independently. This multicolor photodiode is formed by three vertically stacked pn junctions as shown in Fig. 2.

The top photodiode lies in a depth of about 0.3 µm and consists of n+ and p-well layer. It is used to detect blue light. The photocurrent of p-well/deep n-well junction, which is used as the middle photodiode (located at around 0.9 µm below the semiconductors surface), is dominated by yellow or green light. The deep n-well and the p-substrate form the deep photodiode which is effective at approximately 4 µm below the silicon surface and is used to detect the photocurrent of the red (and the near infrared NIR) light.[11] The current of the deep photodiode will not be affected by the photocurrent from the green and the blue light, although the blue and green detector currents generated by the top and middle photodiodes contain a small portion of the photocurrent from the red light. However, since the red detector is much thicker than the blue one (and the green one) most of the red light current will be generated in the deep junction.

C. Multicolor Photodetector for Data Communication

For multicolor optical data communication, both the data rate and the cross-coupling are the important

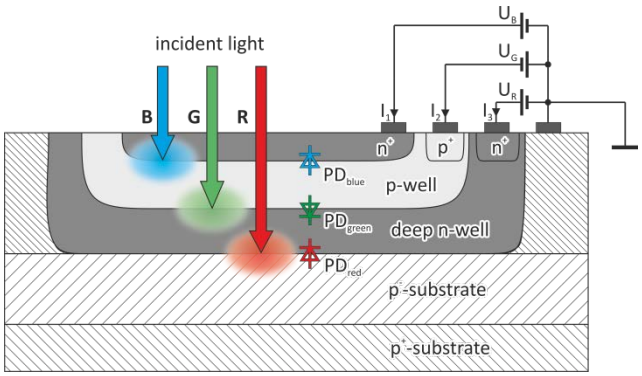

Figure 2. Vertically stacked multicolor photodiode

parameters. The data rate is mainly dominated by the frequency response of the photodiode whereas the cross-coupling between adjacent detectors for the triple junction detectors is determined by the pn junction capacitance. We will discuss these two parameters in this section.

- Frequency Response

The frequency response (bandwidth) of the photodiode mainly depends on three factors as follows, the carrier drift time t, the minority carrier diffusion and pn-junction capacitance and series resistance.

Firstly, we will discuss the carrier drift time, which determines the obtainable speed of the photodiode. It is proportional to the width of the space charge region W and inversely proportional to the carrier drift velocity v. The drift velocity v depends on the carrier mobility µ and the electric field E. Furthermore, the carrier mobility µ depends on the doping concentration whereas also the distribution of the electric field is determined by the doping concentration and the reverse bias voltage.[12] Because the photodiode is fabricated in a standard 0.6 µm CMOS technology the doping concentration of each layer is fixed, so the effect of the doping concentration cannot be changed. As a result we are mainly concerned on the reverse bias voltage. Regarding this condition, we can conclude that a larger the reverse bias voltage leads to a faster photodiode.

In addition, the maximum data rates DR of optical receivers can be estimated by the rise time t_r and fall time t_f of the drift time t in an aggressive way to be:

$$DR = \frac{1}{2t_r} = \frac{1}{2t_f} \quad (1)$$

And the relation (for a first order low pass system) between the rise time and the -3dB bandwidth BW is as follows:

$$BW = \frac{0.35}{t_r} \quad (2)$$

Therefore we can estimate the maximum data rate as a function of the -3dB bandwidth.

$$DR = \frac{1}{2t_r} \approx 1.5BW \quad (3)$$

In conclusion, by measuring the -3dB bandwidth of the photodiode we can estimate the maximum data rate of the communication system.

Secondly, we will discuss carrier diffusion which happens in regions of the semiconductor where no electric field is present. In a normal PIN photodiode two field-free regions have to be considered: The top electrode and the heavily doped substrate. For this triple junction photodiode, the heavily doped surface region is not very thick and thus the diffusion there has no dominant influence. More critical is the region in the depth of the semiconductor below the edge of the space charge region. Since diffusion will reduce the speed of the photodiode we should avoid or at least reduce the carrier diffusion, this can be achieved by using light with short wavelength to avoid photo generation in deep region. Basically this is what we do in the multicolor triple-junction photoreceiver (blue, green light). Another possible way to reduce diffusion is to apply a large reverse bias voltage (across the photodiode) to increase the thickness of space charge region.

Finally, the pn junction capacitance and the total series resistance will be discussed which reduce the speed of the photodiode like an RC time constant. The total series resistance is the sum of the photodiode resistance itself, the wire resistance and parasitic effects in the semiconductor. Usually the last one cannot be neglected when relevant photocurrent flows through low doped regions. The pn junction capacitance mainly depends on the reverse bias voltage (which determines the space charge region thickness) and the size of the photodiode. Therefore we can reduce the diode size and increase the reverse bias voltage to reduce the effect of pn junction capacitance and series resistance.

Summarizing, by applying an appropriate reverse bias voltage across the triple junction photodiode and reducing the area of photodiode, we can get a faster photoreceiver for optical communication.

- Signal Coupling

Apart from the inherent speed of the photodiode, we should also consider the pn junction capacitances which will largely affect the different color signals in the triple junction photoreceiver. The larger the capacitances are, the slower is the complete receiver. Also the effects of signal cross coupling get larger.

The three adjacent space charge regions are formed by three vertically pn junctions, which lead to three adjacent capacitances. The model of the complete photodiode and the input impedances of the amplifiers are shown in Fig 3. C_{PD} presents the pn junction capacitance of photodiode, I_{blue}, I_{green}, I_{red} present the photocurrents flowing through the photodiodes, R_s presents the series resistance and R_I and C_I present the load resistance and load capacitance.

From Fig.3 we can find that the photocurrent generated by blue light will be coupled to the photocurrent from green light. The photocurrent of the green light will be coupled to the photocurrent generated by blue light and the red light. And finally the photocurrent generated by red light will be coupled to the green light. The cross-coupling will largely affect the three independent signals and reduce the maximum speed of the data communication.

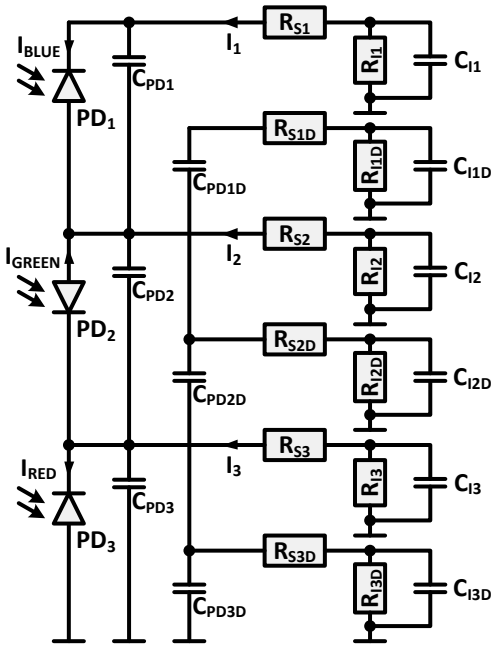

Figure 3. The equivalent circuit of the photodiode with the receiver input impedance

To reduce the cross-coupling of the photocurrents we can reduce the value of the capacitance by increasing the reverse bias voltage. However the reverse bias voltage will be limited on one hand by the used technology and on the other hand by the circuitry of the input stages of the receiver. We should apply the maximum possible reverse bias voltage across the photodiodes.

The pn junction capacitance together with the load (and series) resistance form an RC low pass filter, and therefore, we can also improve the situation by reducing the load resistance. This load resistance depends on the input resistance of transimpedance amplifier input stage. Therefore, we design a transimpedance amplifier with very low input resistance by increasing the gain of the transimpedance amplifier and reducing the feedback resistance.

In conclusion, we can reduce the coupling effects by reducing the input resistance and increasing the reverse bias voltage within the allowed limits.

Based on the discussion above, we can conclude that the reverse bias voltage is a very important parameter for the photodiode. To increase the speed of the photodiode, a large reverse bias voltage should be applied to the photodiode. Also to reduce the capacitance a higher reverse bias voltage would be useful.

On the other hand, since the thickness of the n+ and p-well layer is very small, the space charge regions of the top and middle photodiodes are very close together. If we apply a large reverse bias voltage on the photodiode a reach-through effect will occur and the multicolor photodiode will not work. Consequently, the reverse bias voltage should also not be too large.

Considering all the factors affecting the data rate of the photoreiver in communication applications, we should bias the triple junction photodetector with an appropriate reverse voltage limited by reach-through effects and the above mentioned circuit limitations. For the current design we have chosen a fixed reverse bias voltage of around 1.0 V for the two top photodiodes and around 2.3 V for the bottom diode. This voltages are applied by using two different types of input stages for the three TIAs. TIA_1 and TIA_3 has an input voltage of 2.3 V and TIA_2 has an input voltage of around 1.3 V (Fig. 1).

III. Simulation Results

This fully integrated multicolor photoreceiver is designed for data communication; therefore, based on the discussion in the sections above the main issues are the pn junction capacitance and AC response of the photoreceiver. We will give the simulation results of pn junction capacitance, the ac response and the eye diagram and the summary of the design parameters.

A. Capacitance of the pn junction

Since the pn junction capacitance which is determined by the reverse bias voltage will largely affect the signal coupling, we measured the pn junction capacitance of a 100 µm² photodiode over different reverse bias voltages as shown in Fig. 4.

We can find, like expected, that the capacitance of the photodiode depends on the reverse bias voltage. The capacitance with 1.6 V reverse bias voltage for the three diodes is 2.7 pF, 3.7 pF and 0.7 pF respectively.

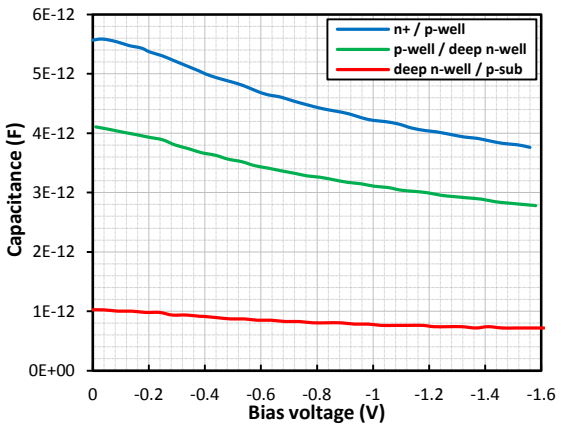

Figure 4. Junction capacitance of 100 µm² photodiodes

B. AC Reponse

We simulate the whole chip with a multicolor photodiode model and given circuit parameters of the package and the PCB to ensure a realistic chip environment. The simplified block diagram of the test circuit with the photodiode model is shown in Fig. 5.

We use a pseudo-random bit sequence PRBS $=2^{15}$-1 to generate photocurrent in the range from 250 nA to

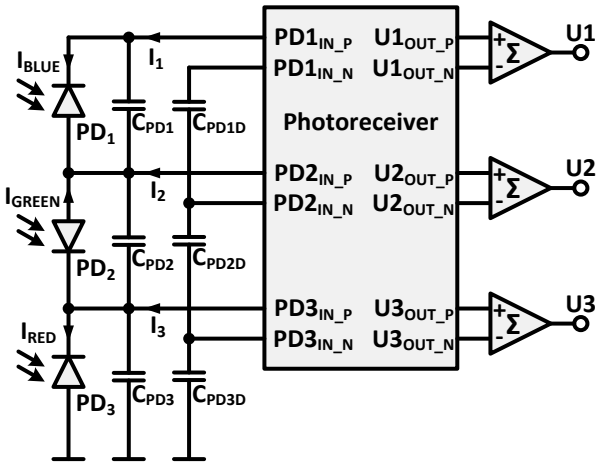

Figure 5. Test circuit with photodiode model

100 µA. The whole chip works at 3.3 V supply voltage and the total power dissipation of the chip is 119 mW with a 300 mV peak to peak output voltage

The AC Response of the blue, green and red light is shown in Fig 6. As we can see from Fig. 6, there are three different channels detecting different colors of light. The bandwidth for the blue, green and red channel is 110 MHz, 135 MHz and 130 MHz respectively, which leads to a maximum data rate up to 200 Mbps per color.

C. Eye Diagram

The eye diagram of three channels with the corresponding light power is shown in Fig. 7, Fig. 8, and Fig. 9. Figures 7-9 show that the 100 Mbps eye diagrams for a blue light power of -28 dBm, a green light power of -27.2 dBm and a red light power of -31.5 dBm are still wide open. They also show a peak-peak voltage of

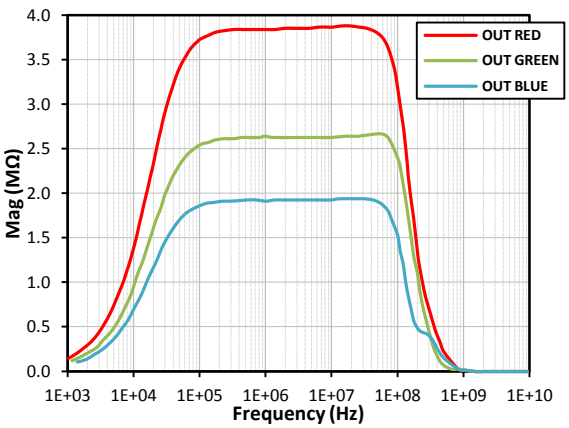

Figure 6. Transimpedance AC response of RGB light

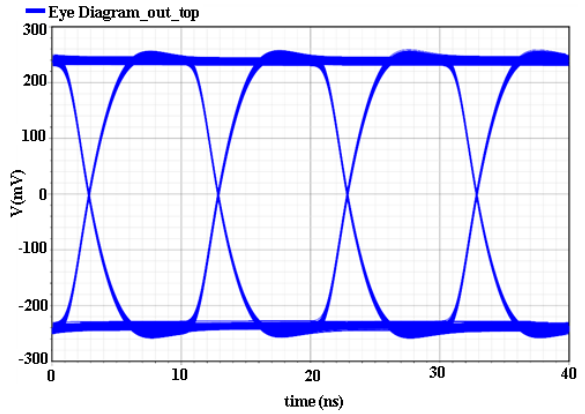

Figure 7. Eye diagram of blue light (P_{opt}=-28 dBm, DR=100 Mbps, PRBS=2^{15}-1, VCC=3.3V)

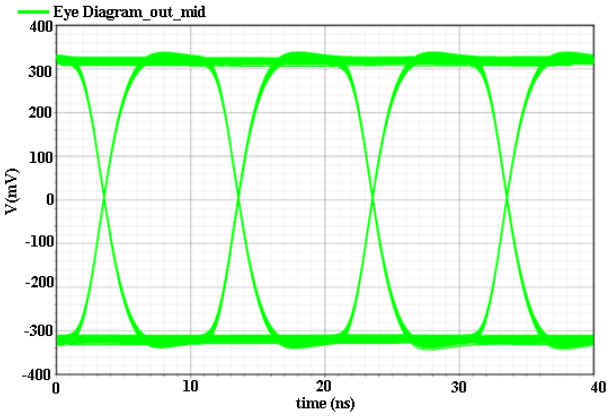

Figure 8. Eye diagram of blue light and green light(Popt=-27.2 dBm, DR=100 Mbps, PRBS=2^{15}-1, VCC=3.3V)

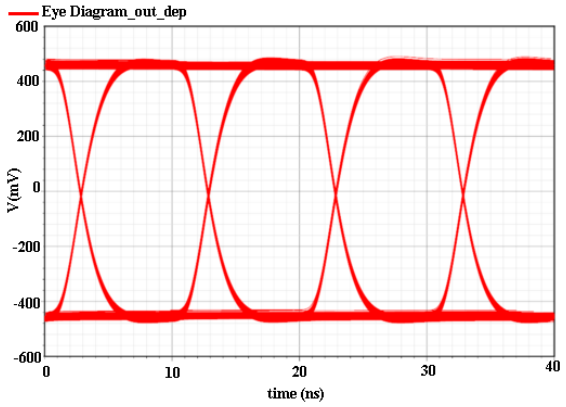

Figure 9. Eye diagram of green light and red light(Popt=-31.5 dBm, DR=100 Mb/s, PRBS=2^{15}-1, VCC=3.3V)

476 mV, 640 mV and 900 mV respectively. From the diagrams even a much higher bandwidth can be expected.

D. Summary of the Design Parameters

Table 1 gives the summary of the design parameters. From table 1 we can conclude that the total power dissipation is only 119 mW at a supply voltage of 3.3 V. The blue, green and red light power can change from -2.0 dBm to -28 dBm, -1.2 dBm to -27.2 dBm, and -5.4 dBm to -31.5 dBm respectively. The maximum data rate of the whole chip can reach up to 200 Mbps per color.

IV. CONCLUSION

We have designed a fully integrated multicolor photoreceiver based on a vertical stacked RGB photodiode used for sensors and optoelectronic integrated circuits. The integrated photodiode fabricated in standard CMOS technology is cheaper compared to external or lateral circuits. Furthermore, since there are no additional bond wires between the photodiode and receiver circuit, the circuit reduce the parasitic effects of the off-chip connection and it is easy to package and handle the device. In addition, the solution improves the electromagnetic interference (EMI). Most apparently, this kind of photoreceiver largely reduces the chip area due to the elimination of bond pads between receiver and photodiode.

The designed photoreceiver can detect the light with wavelength ranging from 400 nm to 900 nm. The whole chip is fabricated in standard 0.6 µm CMOS technology without any process modifications. Based on the simulation results, we have found that this kind of photoreceiver can meet the requirements of color detection and data rates up to 200 Mbps per color.

TABLE I. SUMMARY OF CHIP PARAMETERS

Parameter	Result
Supply voltage	3.3 V
Power consumption	119 mW
Responsivity_blue	0.16 A/W
Responsivity_green	0.13 A/W
Responsivity_green	0.35 A/W
Light power range_blue	-28 dbm---(-2.0 dbm)
Light power range_green	-27.2 dbm---(-1.2 dbm)
Light power range_red	-31.5 dbm---(-5.4 dbm)
Maximum Data rate	200 Mbps
Bandwidth_Top	117 MHz
Bandwidth_Mid	139 MHz
Bandwidth_Deep	130 MHz
Output swing top	476 mVpp
Output swing mid	640 mVpp
Output swing deep	900 mVpp
Equivalent Input Noise_top	46 nA
Equivalent Input Noise_mid	80 nA
Equivalent Input Noise_deep	40 nA

Abstract - In this paper frequency-modulated sensor for color detection based on reflective color sensing is proposed. Sensor consists of an RGB LED and a phototransistor. Red, green and blue LEDs are excited at different frequencies. In this way detection of the reflected signal is achieved with only one photodetector and three bandpass filters. Color information from the sensor is obtained using digital signal processing of frequency modulated signal on personal computer (PC). The signal is transferred to PC using analog to digital converter on PC sound card.

I. INTRODUCTION

Recently, the use of color sensors is expanded in many fields. Important areas of application of color sensors are industry, science, chemistry, agriculture, robotics, art and many others. Color detection is also important in some specific applications. A rapid, convenient and in situ applicable colorimetric pH sensor constructed based on a dual light-emitting diode (LED) system is presented in [1]. A colorimetric sensor for odor visualization and discrimination is given in papers [2, 3].

In the field of microfluidic measurements color detection is also very important. A microfluidic-colorimetric sensor with some theoretical and experimental results for fast and continuous monitoring of air pollution is presented in [4]. A new sensor system, specifically designed for the characterization of wines, which combines three sensory modalities: an array of gas sensors, an array of electrochemical liquid sensors, and an optical system for color measurement is presented in [5]. Organic vapor detection using a color-difference image technique for distributed Bragg reflector structured porous silicon is reported in [6]. Sensitive chemical sensor using birefringent porous glass for the optical-colorimetric detection of volatile organic solvent vapors is given in [7].

A coherent description and interpretation of the principles of three basic measuring methods for identification, classification and evaluation of the color of light reflecting samples containing iron oxides is presented in [8]. Multicolored objects recognition invariant to a substantial change in viewpoint, object geometry and illumination is reported in [9].

Sensor implementations based on RGB (Red, Green and Blue) LED are reported in [10-12]. In this paper hardware and software implementations of a low-cost reflective color sensor based on RGB LED and frequency modulation are presented. Hardware implementation of the sensor is based on RGB LED modulated at three different frequencies. Software solution which determines color is based on additive RGB color model. Additive systems, such as stage lights and color television monitors, generate colors by additive mixing of light from three light sources, such as individual lights or electron guns [13]. Such systems are typically modeled by the RGB color cube. A color in the color cube model is a three-dimensional vector whose coordinates specify the amounts of red, green, and blue component [13].

The advantages of proposed sensor in relation to the others are its simplicity, low-cost and simple and fast determination of the color of investigated object. Sensor described in [10] is similar to proposed one, but it is more complex, and has lower speed of operation. Mentioned sensor is based on neural networks using an artificial intelligent technique, and sensor determines the color of object for 3 seconds. The sensor produced here has better performance in relation to mentioned artificial intelligent sensor in terms of higher speed of color determination. Our sensor determines color instantaneously, and has simpler hardware and software design.

II. PRINCIPLE OF THE SENSOR OPERATION

The color of an object depends on both the physics of the object in its environment and the characteristics of the eye and brain perception. Physically, it can be said that objects have the color of the light leaving their surface, which normally depends on the spectrum of the incident light and the reflectance properties of the surface. Also, color depends on the angle of the illumination of the object and viewing angle. The colors of opaque objects are caused by selective reflection of certain wavelengths and absorption of others.

Color sensors in some way measure the object properties to determine its color. However, there are two commonly used types of color sensors. The first is color sensor based on recording and processing object with a camera [14] and second is reflective color sensor [10, 12]. In this paper a low-cost reflective color sensor is proposed. A typical reflective color sensor consists of an object whose color is measured, a light source that illuminates the object and a detector that captures the reflected light from the object. The most important parts of the design are the light source and the photodetector.

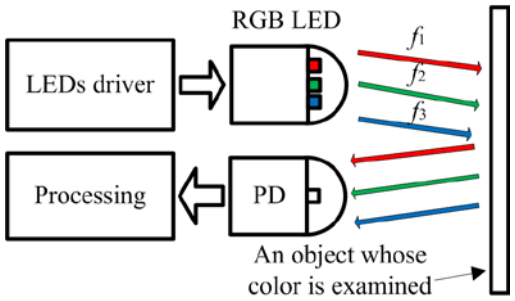

Figure 1. A principle scheme of reflective color sensor using three light emitting diodes - LEDs generating RGB colors and PD - photodetector

In practice, there are two most common implementations of reflective color sensor. The first one uses a broadband white-light source and three photodetectors with different spectral characteristics, usually accomplished using optical filters. The second one uses three light sources at different wavelengths (typically RGB LED) and one photodetector with a wide spectral response. The sensor described in this section belongs to the second group and its general structure is given in Fig. 1.

There are several methods for multiplexing RGB LEDs. The most common types of multiplexing are a time-division and frequency multiplexing technique. The main drawback of time-division in this application is low speed, in comparison to frequency modulated. In this paper the frequency modulated red, green and blue component of RBG LED is used.

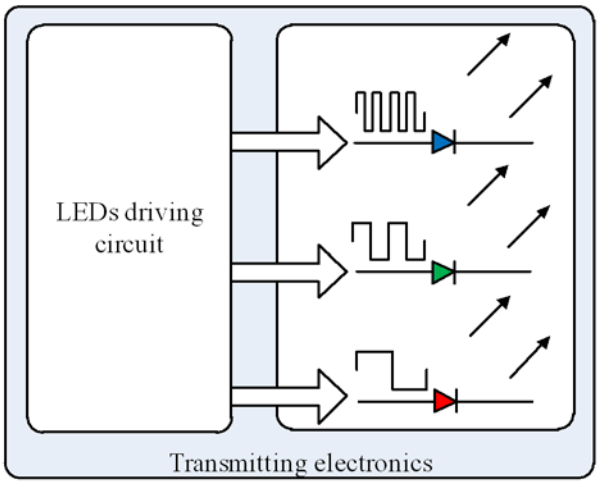
III. SENSOR IMPLEMENTATION

Sensor implementation can be divided into two parts: hardware and software. Hardware part is designed using analog electronics and it consists of circuit for driving the LEDs and an amplification and filtration stage for signal processing from photodetector. For implemented sensor, software is crucial. Software receives data from analog part of sensing electronics via sound card. Sound card digitizes analog signal via internal analog to digital converter. Received digital data are further processed in LabVIEW software package.

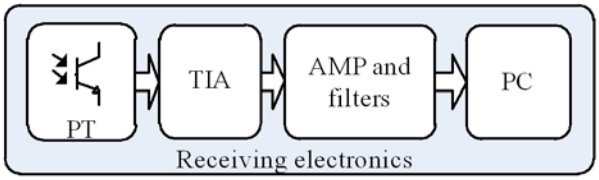
A. Electronics of proposed sensor

The block diagram of sensing electronics of the resulting sensor can be divided into two blocks, electronics for transmitting and receiving the optical signal. Transmitting and receiving block diagrams are shown on Fig. 2a) and Fig. 2b), respectively.

A low-cost RGB LED is used for sensor implementation as the light transmitter. For this purpose RGB LED in junction with common cathode is used. All three LEDs are packaged in the same casing. The peak wavelengths of LEDs are located at λ_{RED} = 635 nm, λ_{GREEN} = 514 nm, and λ_{BLUE} = 472 nm. The characteristics of the RGB LED obtained by the measurements are given in Table I, and spectrum of used RGB LED is given in Fig. 3. Spectrum is measured with Thorlabs SP1 USB spectrometer, which detects light spectrum in range from 400 to 800 nm.



a)



b)

Figure 2. a) The block diagram of transmitting electronics, b) The block diagram of receiving electronics: PT – Phototransistor, TIA – Transimpedance amplifier, AMP - Amplifier, PC – Personal Computer

Red, green and blue components of used RGB LED are excited at 1.3 kHz, 5.7 kHz and 3.2 kHz, respectively.

Pulsed signal is obtained by Schmitt trigger circuit. Because the signal is pulsed in the selection of frequencies, the influence of the higher harmonics of pulsed signal was taken into consideration. Higher harmonics of pulsed signal which excite the LEDs may affect an error if some of the higher harmonics on some LED overlaps the fundamental frequency at which the other LED is modulated. For example, if chosen LED modulation frequencies are 1 kHz, 2 kHz and 4 kHz, then second harmonic of the 1 kHz pulsed signal has an impact on second LED (modulated at 2 kHz) and the fourth harmonic has an impact on third LED (modulated at 4 kHz). Also, in that case the second harmonic of second LED has an impact on third LED (modulated at 4 kHz). This effect can be seen during the signal demodulation after reflection from the object. To avoid the impact of these harmonics on sensor performance, mentioned frequencies are chosen in order to prevent overlap of some higher harmonics with the fundamental harmonics

TABLE I. MEASURED VALUES OF THE RGB LED USED IN SENSOR DESIGN

LED color	***Measured wavelength [nm]***	***Full width at half maximum -FWHM [nm]***	***Modulated frequency [kHz]***
Red	635	12	1.3
Green	514	21	5.7
Blue	472	21	3.2

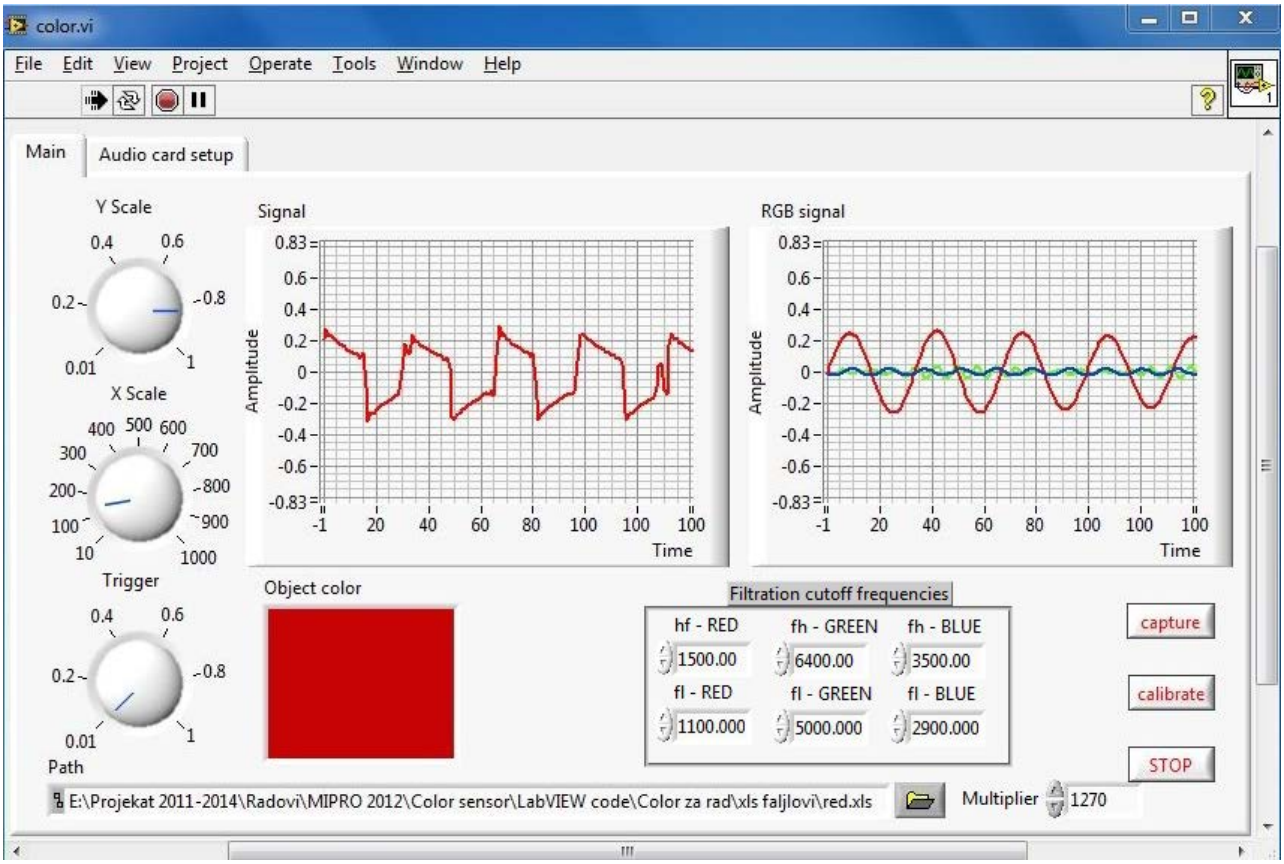


Figure 3. The implemented LabVIEW software package for color sensing with an example for red object color detection

of pulsed signal on the LEDs.

As photodetector, BPW40 phototransistor is used. Phototransistor BPW40 that works with transimpedance amplifier (TIA) is chosen because its characteristics are suitable for this sensor and has the same dimensions as used RGB LED. The angle of half sensitivity of used phototransistor is ±20°.

The crucial blocks in the receiving electronics are amplifier and filters. In the optical receiving circuit 50 Hz notch filter is implemented in order to eliminate 50 Hz noise which may occur due to city power supply. For this filter twin T filter configuration is used. In addition to notch filter in receiving electronics, there are two additional filters, lowpass and highpass filters. The purpose of the highpass filter is to remove DC component of the received optical signal. Lowpass filter is used to remove high frequency noise in the received optical signal. Amplifier is used for additional amplifying of filtered signal. Transimpedance amplifier, filters and amplifiers are all implemented using MCP6022 and MCP6024 rail-to-rail operational amplifiers, produced by Microchip Inc.

B. Software for color measurement

After amplification and filtration, signal from photodetector is transferred via sound card to the PC. An application for further signal processing and color recognition is implemented in LabVIEW software package. As already mentioned implemented software communicates with electronics via sound card and displays signal after processing. The advantage of this method for sampling and data processing is that it does not require an additional hardware (e.g. microcontroller). In this way we can use all the power that PC provides for signal processing. LabVIEW offers powerful signal processing toolkits, which is used in this paper.

The signal acquired to PC via the sound card is decomposed into red, green and blue components of the signal, using three software bandpass filters.

An application in LabVIEW software package for color sensing with an example for red object color detection is presented in Fig. 4. Received amplitudes of

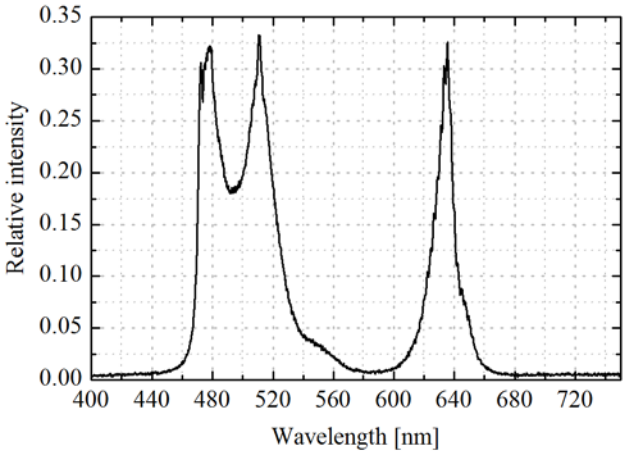

Figure 4. Spectrum of used RGB LED obtained by measurements

modulated signal are converted by using LabVIEW function *RGB to color*. RGB to color function summarizes received red, blue and green components in one data (4 Bytes) and determines color by looking at the RGB color table. It can be clearly seen that application has functions for adjusting amplitude and time scale as an oscilloscope. Also, the application gives the possibility to manually adjust high and low cutoff frequencies for each of the bandpass filters. After filtering, the measured red, green and blue components are additively mixed based on the RGB color model in order to obtain true object color.

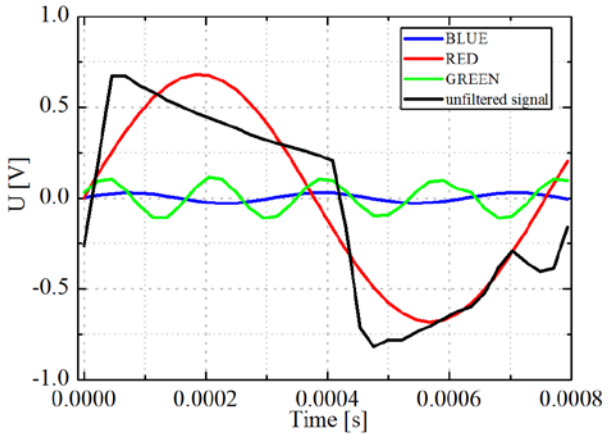

Figure 5. Signals for red colored paper as object

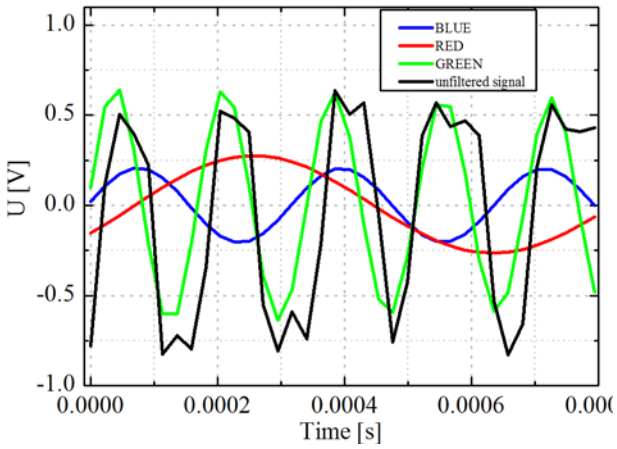

Figure 6. Signals for green colored paper as object

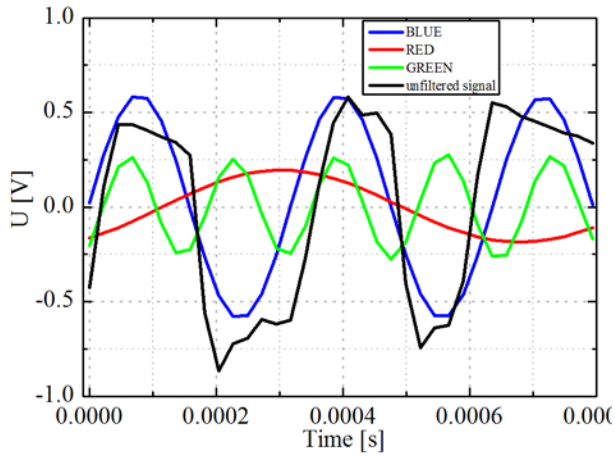

Figure 7. Signals for blue colored paper as object

C. *Sensor calibration*

Only when the sensor fabrication is completed, calibration must be done. Calibration of the sensors is done in two phases. Firstly, the amplitudes of red, green and blue components of the signal are set to be equal when a white object is placed in front of the sensor. This operation is done on the analog electronics where knobs for adjusting intensity of each LED are located. Second phase of calibration is performed in software. This phase of calibration is done by clicking on the button “calibrate” in the application, when there is no object in front of the sensor. In this way application stores in memory all values that may exist due to noises or crosstalk. These values are later subtracted from the measured signals in order to reduce the influence of noise.

IV. RESULTS AND DISCUSSION

The sensor is tested for various objects with different colors. The results have shown that produced sensor is capable of differentiating between shades of the same color. For testing, colored paper with different colors has been used. In Fig. 5, Fig. 6 and Fig. 7 signals for red, green and blue colored papers detection are shown, respectively. It is important to say that colored papers used in experiments are not reference colored papers. Colored papers used in experiments were predominantly red, blue and green color. Therefore from the results shown in Fig. 5, Fig. 6 and Fig. 7 relatively significant presence of more than one color component can be noted.

From all three graphs can be clearly seen that the extraction of red, green and blue signal components from the input signal was successful. The sensor is able to detect different colors in the proximity up to range of 10 cm. However, it has been noticed that sensor gives the best performance at distance where it has been calibrated using white object. The photograph of the implemented sensor is presented in Fig. 8.

Figure 8. Photograph of the implemented color sensor

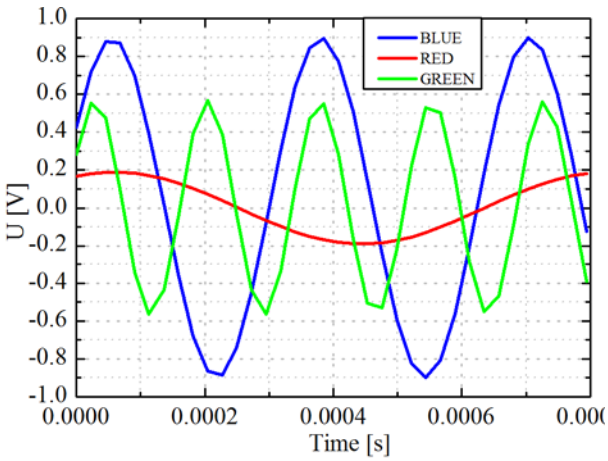

Figure 9. Signals for light blue colored paper as object

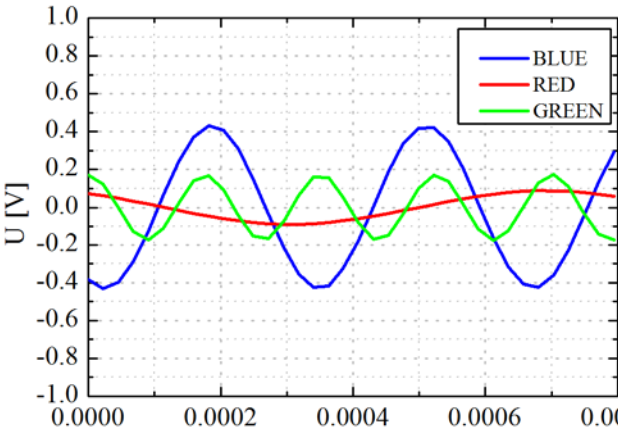

Figure 10. Signals for dark blue colored paper as object

Some results which demonstrate an example of an additive mixing based on the RGB color model are shown in Fig. 9 and Fig 10. Also, these graphs demonstrate sensor capability to differentiate shades of the same color.

V. CONCLUSION AND FUTURE WORKS

This paper presents reflective color sensor based on frequency modulation. Analog signals, which are via sound card brought to the computer, were successfully converted to RGB colors of object. Additive RGB model used in this paper provides the simplest color extraction from detected amplitudes of R, B and G components. Some further analysis and improvements of color sensor based on RGB LED can be obtained by using HSV and HSL representations of RGB color model. Completed sensor can be applied in various fields such as industry, chemistry, environmental protection etc. The authors' future work will be based on the application of this sensor for testing contaminated liquids in environmental protection. The main advantages of developed sensor are its low-cost, simplicity, and usage of computer for data processing, which minimizes the use of electronics.

Abstract - In this paper a realization of the optical beam profiler system based on a low-cost web camera and great capabilities of LabVIEW software package is presented. The system provides possibilities of measuring, capturing, displaying, and recording various parameters of the optical beam, such as spatial profile, beam quality, intensity measurement and so on. Implemented software enables various types of image processing, which makes measuring easier and more accurate. The applications of the developed system include: laser monitoring, nonlinear optics, far-field measurement, education and so on.

I. INTRODUCTION

In laser applications, the beam profile provides valuable information for the most efficient use of the laser [1], [2]. For some lasers and applications, monitoring of laser beam profile may only be necessary during the design or fabrication phase of the laser. However, sometimes it is necessary to monitor the laser profile continuously during the laser operation. Some industrial laser applications require periodic beam profile monitoring in order to eliminate producing scrap when the laser degrades. In other applications, such as medical, the practitioner has no capability to tune the laser, and the manufacturers measure the beam profile during design to ensure that the laser provides reliable performance at all times. In scientific applications, it is also very important to monitor the beam profile, particularly when examining nonlinear optical properties of the materials. Some materials intend to perform distortion of the laser beam, or act as a lens to focus or scatter the laser beam. In such cases high quality beam profiling is of key importance. A novel z-scan technique for measuring optical non-linearities based on laser beam radius measurement is reported in [3].

Laser beams produce light with many characteristics that are unique in comparison to other light sources, such as coherence, monochromatic nature, unique spatial power distribution and ability to be focused to extremely small spots. One of the fundamental parameters that indicates how a laser beam will behave in an application is its spatial intensity distribution. As the laser beam propagates, its spatial intensity distribution will change in space and time. Characteristics such as propagation of the beam through space, concentration and collimation of the light are all significantly affected by its spatial intensity distribution. Theory can sometimes predict the behavior of the beam but tolerances in manufacturing of the lenses and mirrors, and ambient conditions, often require an experimental confirmation. Influence of intensity distribution of laser beam on the properties of nanoparticles obtained by laser ablation of solids in liquids is reported in [4]. Influence of the spatial laser intensity distribution on laser nitriding of iron is presented in [5].

In order to select the best optics for a particular laser application, it is important to understand the basic properties of Gaussian beams. A beam quality factor or M^2 (also called beam propagation factor) has been defined to describe the deviation of the laser beam from a theoretical Gaussian [6]. An ideal theoretical Gaussian beam has $M^2=1$, whereas for real laser beams $M^2>1$. M^2 factor can be calculated from following equation:

$$M^2 = \frac{\pi \cdot w_0 \cdot \theta}{\lambda}, \qquad (1)$$

where θ is the beam divergence half angle, w_0 is the beam waist radius at the $1/e^2$ times the maximum value point and λ is the laser wavelength. The beam propagation factor (M^2) is a highly useful parameter for characterizing the optical quality of real laser beams.

High quality beam profile monitoring is necessary not only in laser applications. Optical fibers are now efficient optical wave guides and are used as transmitting media for the power and information. Transmitted information depends on spatial optical distribution. Fiber output beam shape study using imaging technique is reported in [7]. Beam profile and image transfer study in the fiber coupling is reported recently in [8]. The changes in output beam power and intensity profile are investigated in that study and important issues such as the role of the air-gap in fiber coupling and core diameters are described. In [9] source light effects in optical fiber output beam imaging is presented. In addition, the recent rapid development of fiber optic sensors opened another area where observing

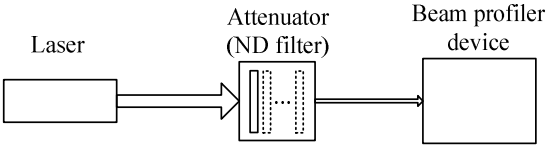

Figure 1. Typical setup for measurement of the laser beam profile

the optical beam profile at fiber output, is also very important.

In this paper an implementation of the optical beam profiler system based on a low-cost web camera and great capabilities of image processing in LabVIEW software package is presented. The system provides possibilities of measuring, capturing, displaying, and recording various parameters of the optical beam, such as spatial profile, beam quality, intensity measurement and so on.

II. METHODS FOR BEAM PROFILING

Typical setup for measurement of the laser beam profile is given in Fig. 1. When measuring the beam profile of a laser, it is nearly always necessary to attenuate the laser beam, at least to some degree, before measuring the beam with an electronic instrument. There are several ways to do this. The most common way is to use neutral density (ND) filter, either absorptive or reflective. Another way, typically used to attenuate high power laser, is to use optical wedges and reflections from uncoated optical glass surfaces. Whichever technique is applied, it is essential that the attenuator does not introduce any distortion into the laser beam.

There are four main types of spatial beam-profiling instrumentation: camera-based systems, pinhole scanners, knife-edge scanners, and slit scanners [10], [11], [12], [13]. Each has specific advantages and disadvantages and measurements that may result in slightly different results.

Knife-edge, slit, and pinhole profilers belong to the mechanical scanning devices. These scanners generate a profile by mechanically moving a knife-edge or an aperture (slit or pinhole) across the beam in a plane orthogonal to the optical axis. The light passing through is measured by a detector and correlated with the position of the aperture as it crosses the beam. This method provides an excellent resolution. One of the main advantages of mechanical scanning devices is that they can be used directly with the beam of medium power lasers with little or with no attenuation because only a small part of the laser power reaches the detector, while the most of it is reflected away from the detector. However, mechanical scanning methods work only on continuous wave (CW) lasers, not on pulsed lasers. Also they have a limited number of axes for measurement, usually only two.

Unlike the mechanical scanners, cameras use two dimensional array pixels as the imaging device. The intensity distribution of a laser or light source is recorded pixel by pixel and displayed as either a topographic or three-dimensional contour plot. The main advantage of such profilers is that they can detect and display any structure that may exist on the profile, and they can be used with both CW and pulsed lasers. Main drawback of this kind of beam profilers is limited resolution to approximately the size of the pixels. Another drawback of camera based systems is extreme sensitivity which requires nearly always attenuation of the laser beam. The two most commonly used cameras are charge-coupled device (CCD) and complementary metal-oxide-semiconductor (CMOS) sensors. Both types of devices

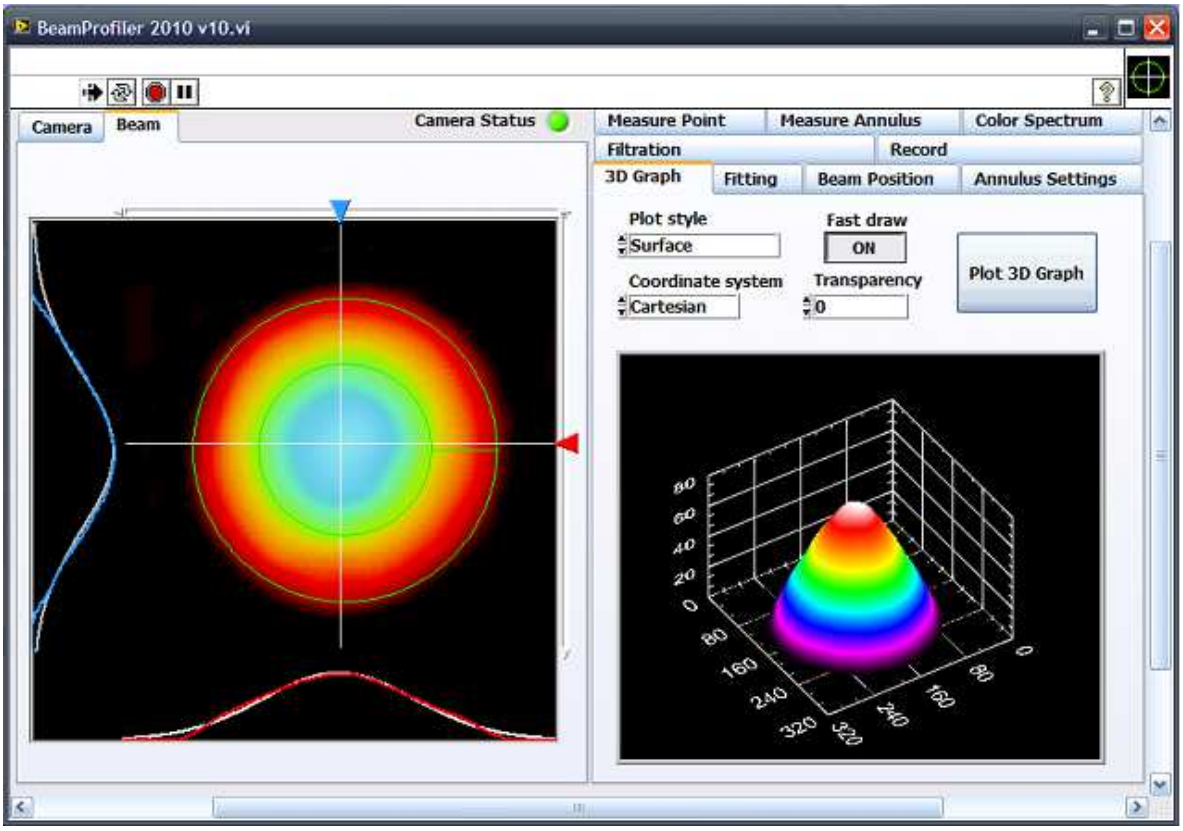

Figure 2. Front panel of the implemented software for optical beam profiling

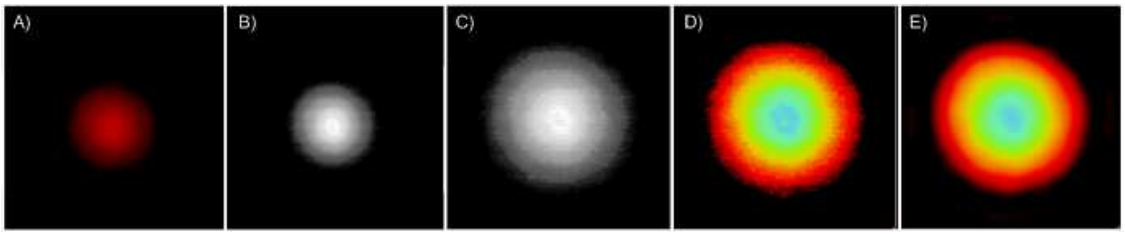

Figure 3. Image processing and filtration: A) Primary image acquired from web camera; B) Image converted into grayscale; C) Resampled image; D) Image displayed in gradient color palette; E) Image after filtration

convert light into electric charge and process it into electronic signals. In general, CCD cameras have a greater dynamic range and lower noise than CMOS cameras. On the other hand, design of CCD camera itself leads to a disadvantage in comparison with a CMOS camera in the case of beam profiling. Saturation and blooming are related phenomena that occur in all CCD image sensors. A CCD image sensor is an analog device. Charge in every pixel is transferred through a very limited number of output nodes (often just one) to be converted to voltage. In such system when finite charge capacity of individual photodiodes, or the maximum charge transfer capacity of the CCD is reached, saturation occurs which may lead to overflow or blooming. Potentially undesirable effects of blooming may be reflected in the sensor output, ranging from white image streaks and erroneous pixel signal values to complete breakdown at the output amplification stage, producing a dark image. With CMOS sensor situation is different. Each pixel has its own charge-to-voltage conversion, which means that every pixel can be read out individually. Therefore, there are no blooming effects. If a pixel gets saturated, neighboring pixels are not affected.

III. LABVIEW SOFTWARE

The visualization and measurement of the beam is a simple task to perform when an image is acquired to a PC. In order to perform the characterization of the optical beam, the system that consists of an inexpensive CMOS web camera and program developed in the LabVIEW software package was implemented. As imaging device Ball Camera from Maxell is used, but any other USB web camera could also be used. In Fig. 2 front panel of the implemented software for optical beam profiling is presented. The system performs real-time image streaming and provides possibilities of measuring, capturing, displaying, and recording various parameters of the optical beam.

There are certain requirements that software for optical beam profiling must satisfy. The most important are the visual representation of the beam, noise filtering and measurements of the spatial profile and optical power of the beam.

A. Beam Visualization

An important property of the beam profiling software is visual representation of the optical beam. A black and white image is basically the same as looking directly at the beam, by representing different intensity levels as colors the operator can more easily distinguish the levels.

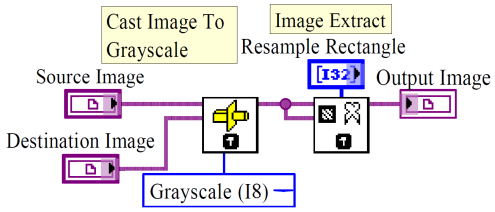

Figure 4. Image conversion and extraction

As it can be seen from Fig. 2 captured optical beam is presented in gradient color palette. An even better way of visualizing the beam is to plot a 3D graph and combine this with colors, which is also possible with implemented software.

B. Image Processing and Filtration

A very important aspect concerning camera-based analyzers is background noise monitoring and subtraction. The implementations of a powerful analytical method to address these issues are an essential feature of an useful beam diagnostic system. In this segment LabVIEW vision module provides a simple solution.

The Fig. 3 shows the appearance of an optical beam through the process of conversion and filtering.

In Fig. 4 block diagram that performs image conversion and extraction is presented.

Before any filtration, color image acquired from camera is transferred into 8-bit grayscale image. The reason for this transformation is that for grayscale images less information needs to be provided for each pixel. In fact, a gray color is the one in which the red, green and blue components all have equal intensity in RGB space, and so it is only necessary to specify a single intensity value for each pixel, as opposed to the three intensities needed to specify for each pixel in a full color image. In addition, grayscale images are entirely sufficient for this application and so there is no need to use more complicated and harder-to-process color images. The primary color image acquired from camera and image converted into grayscale are displayed in Fig. 3 A and Fig. 3 B, respectively.

After conversion to grayscale, region of interest (where optical beam is located) is extracted and resampled into a new image. In this way only a portion of image where optical beam is located is submitted to further analysis. Image after extraction is presented in Fig. 3 C.

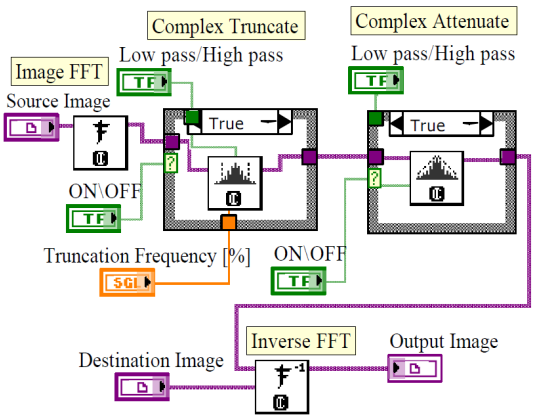

Figure 5. Complex truncation and attenuation of an image

Resampled image is submitted for further processing and filtration. Implemented software provides possibilities of image filtration, performing grayscale morphological transformations, computing negative of an image, performing image equalization and so on. What proved to be the most useful in beam profiling is the basic image filtration in frequency domain. In Fig. 5 the block diagram of the software that performs complex truncation and attenuation of an image is presented. The image is first transformed into complex domain by using FFT, in which high frequencies are grouped at the center, while low frequencies are located at the edges. The basic feature in images is the edge, the line separating one object or region from another object or region. Since an edge is composed of a wide range of frequency components, trying to modify an image by manipulating the frequency spectrum is generally not productive. Image filters are normally designed in the spatial domain, where the information is encoded in its simplest form. But, smoothing and edge enhancement operations in the spatial domain correspond to high-pass and low-pass filters in the frequency domain. This is exactly what is done in Fig. 5 using functions complex truncate and attenuate. Images before and after operations truncate and attenuate are presented in gradient color palette in Fig. 3 D and Fig. 3 E, respectively.

C. *Measurement of the Beam Width and Power*

Implemented software provides possibilities of measuring the intensity at any point of the beam, as well as measuring the power inside predefined ring (annulus) or circle. Software measures intensity in the point that is located in cross section of the vertical and horizontal cursors displayed with white line in Fig. 2. Also, it should be noticed that there are two concentric circles in Fig. 2. By adjusting their radiuses it is possible to measure beam power inside annulus or circle.

There are several definitions of beam width: FWHM, D4σ width, D86 width and $1/e^2$ width. The simplest way to define the width of a beam is to choose two diametrically opposite points at which the irradiance is a specified fraction of the beam peak irradiance, and take the distance between them as a measure of the beam width. An obvious choice for this fraction is 1/2, in which

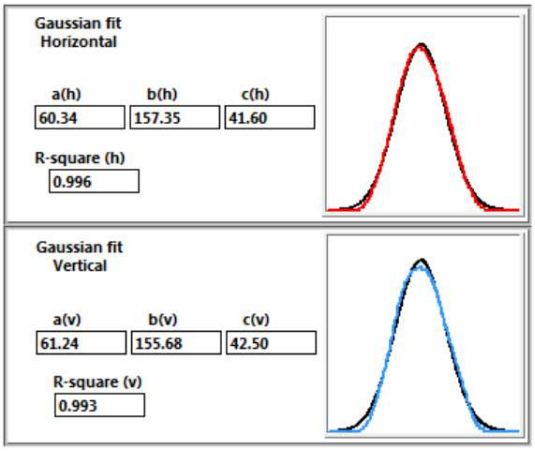

Figure 6. Best Gaussian fit of the spatial intensity distribution along horizontal (h) and vertical (v) axes: a-amplitude, b-center, c-standard deviation of the Gaussian function

case the diameter obtained is the full width of the beam at half its maximum intensity (FWHM). D4σ is abbreviation for the diameter that is four times σ, where σ is the standard deviation of the horizontal or vertical marginal distribution. In many cases, it makes more sense to take the distance between points where the intensity falls to $1/e^2$ times the maximum value. The D86 width is defined as the diameter of the circle, centered at the centroid of the beam profile and contains 86% of the beam power. Using previously described cursors and annulus options it is possible to measure all of these widths.

Another useful feature is provided with the implemented software. For spatial intensity distribution along horizontal and vertical axes software gives best Gaussian fit, directly giving the peak value in the beam, position of the center of the beam, standard deviation and goodness factor (Fig. 6).

IV. EXPERIMENTAL RESULTS

A. *Standard Application: Measurement of the laser beam profile*

Recorded intensity profiles along vertical and horizontal axes for helium neon laser are presented in Fig. 7. In Fig. 7 A recorded intensity profile and best Gaussian fit along vertical axis are presented. In Fig. 7 B recorded intensity profile and best Gaussian fit along horizontal axis are presented. Intensity profiles are measured for the helium neon HRR005 laser produced by Thorlabs, Inc. For both profiles good Gaussian fit is obtained with R^2=0.998 that corresponds with theoretical results for helium neon laser. In technical documentation for HRR005 is specified that laser has a $1/e^2$ beam diameter of 570 µm. Beam diameter of 585 µm is obtained using implemented system. Comparing to data specified in technical documentation of the laser, it can be concluded that measurement error is less than 3%.

B. *Non-standard Application: Measurement of the optical fiber output shape*

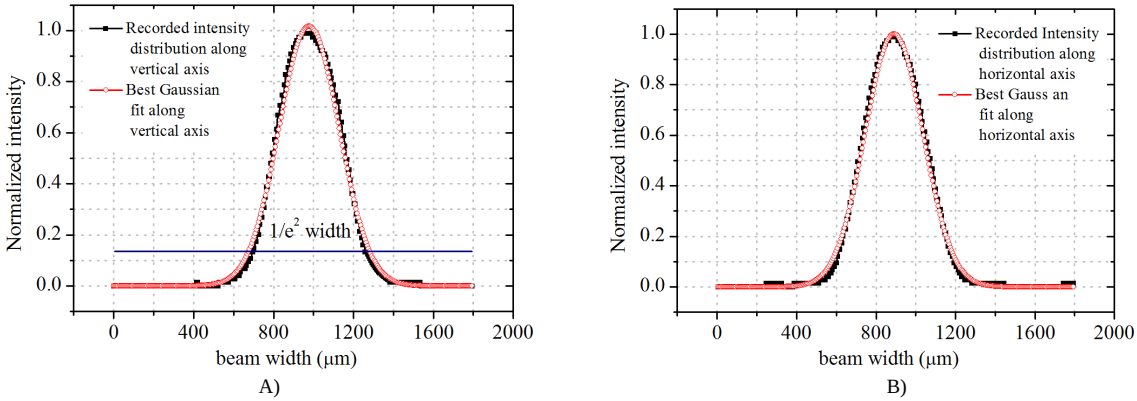

Figure 7. Recorded intensity profiles along vertical and horizontal axes for helium neon laser: A) Intesity profile along vertical axes; B) Intesity profile along horizontal axes.

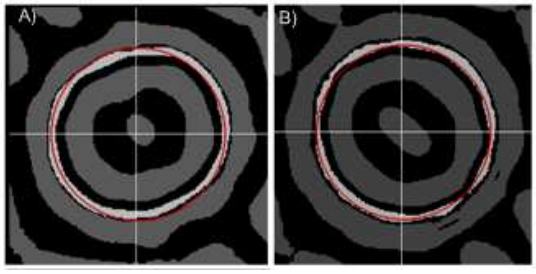

Figure 8. Measurement of the optical fiber output shape: A) Optical fiber output after cutting and before polishing; B) Optical fiber output after polishing

One of the non-standard applications of the software is to determine the shape of the optical fiber output, which can be used in examining the quality of polishing of optical fiber. Processed images of optical fiber before and after polishing are presented in Fig. 8. For this purpose standard 1 mm plastic optical fiber with circular output shape is used. By using possibilities of image processing provided by implemented software, edges of the optical fiber are extracted. Optical fiber output shape after cutting and before polishing is presented in Fig. 8 A. As it can be clearly seen optical fiber output has an elliptic shape due to squeezing of the fiber during cutting. Optical fiber output shape after polishing is presented in Fig. 8 B. After polishing optical fiber output gets circular shape.

V. CONCLUSIONS

A sophisticated system for optical beam diagnostics is presented. Comparative characteristics of the proposed and typical commercial optical beam profilers are presented in Table I. The system provides various possibilities of measuring, capturing, displaying, and recording different parameters of optical beams, such as spatial profile, beam quality, intensity measurement and so on. Implemented software enables various types of image processing, which makes measuring easier and more accurate. The system can be used in standard beam profiling applications such as measurement of the laser beam profile. Practical results have shown that it is possible to determine the width of the laser beam with an error less than 3%. Additionally, the system may be employed in some non-standard applications such as described measurement of the optical fiber output shape.

Abstract - In this paper, the quality factor of a tunable piezoelectric actuator based MEMS resonator is analyzed. The piezoelectric effect is the transfer of electric energy to mechanical energy and vice versa which arises in many crystalline materials. A tunable piezoelectric actuator based resonator consists of a cantilever beam actuated by a piezoelectric device mounted on the beam. A piezoelectric device can actuate a cantilever beam by applying an AC voltage over the device. The cantilever beam itself has resonant modes that causes peaks in the vibration when the frequency of the applied voltage matches the resonance frequency of each mode. If another piezoelectric device is attached to the cantilever, it is possible to tune the resonance by connecting that device to a passive external circuit. The multilayered structure created in a tunable piezoelectric actuator causes a discontinuity in thermal transport across the structure, altering the thermoelastic behaviour of the resonator. Applying the principle of superposition, the overall frequency dependent quality factor of tunable piezoelectric actuator can be calculated and it shows two minima compared to that of simple fixed-fixed beam resonators. The Q Factor analysis of the actuator is done by a high end software COMSOL Multiphysics.

Keywords- Thermoelastic damping, Eigen frequency analysis, Q Factor, Simple fixed-fixed beam resonators, Tunable Piezoelectric Actuator.

I. INTRODUCTION

MicroElectroMechanicalSystem (MEMS) technology is a promising technology for low-loss, high linearity RF applications[1]-[4]. Piezoelectrically transduced micro resonators have become an attractive research topic in recent years since it has potential applications in ultra-small mass detectors, bio-sensors, RF filters and high frequency micro oscillators. Compared with electrostatically actuated and sensed capacitive silicon micro resonator, piezoelectrically transduced micro resonator exhibits better impedance matching. Piezoelectrically transduced micro resonator also provides better power handling capability than capacitive type since low driving-voltage of several hundreds of millivolts is enough for resonator actuation, which facilitates the integration of micro resonators with CMOS signal processing circuits. The main advantage of MEMS resonators lies in the possible integration onto the silicon based IC platforms.

MEMS resonators are positioned as potential competitors to quartz crystal resonators[5][6]. For all the applications, it is important to design and fabricate micromechanical resonators with very high quality factors (Q factors) or very little energy loss [2]-[4].

Q factor is defined as the ratio of total system energy to dissipation that occurs due to various damping mechanisms[7].The different energy dissipation mechanisms exist in MEMS systems are air-damping, squeezed-film damping, acoustic radiation from the supports of the beam (also called anchor or clamping losses), damping due to crystallographic defects (such as dislocations twins and grain boundaries) and thermoelastic damping [8]. Various energy dissipation mechanisms are classified as extrinsic and intrinsic. Extrinsic energy losses can be minimized by changing the design or operating conditions of the systems. For example, operating the device in vacuum and designing nonintrusive supports reduces air-damping and clamping losses, respectively. Thermoelastic damping is considered to be one of the most important factors which causes energy dissipation due to the irreversible heat flow of resonating structures in the micro scales. In this paper, the Q factor for thermoelastic damping is investigated in a tunable piezoelectric actuator based resonator and compared it with that of a simple fixed-fixed type resonator.

To achieve ultra-high resonator sensitivity, high quality factor (Q factor) is most desirable in resonator design and fabrication. However, up to date, Q factor of piezoelectrically transduced micro resonator is still lower than that of conventional capacitive type even under atmospheric pressure [7][8], where air damping is believed much larger than other energy dissipation mechanisms. It limits its application on occasions when both ultra-high sensitivity and atmospheric environment are required, such as chemical vapor/molecule detection [4] and living cells observation [9].In this paper, in order to better understand the energy dissipation mechanisms in piezoelectrically transduced micro resonators at atmospheric conditions, which is believed more complex due to electromechanical coupling in piezoelectric thin film and multi-layered device structure, Pb(Ti, Zi)O3 (PZT) thin film transduced micro cantilevers with PZT is fabricated. Then their Q-factors were investigated and studied. Here, (100) oriented PZT thin film was chosen as the electromechanical conversion medium due to its excellent mechanical and piezoelectric properties.

II. Theory of Thermo Elastic Damping (TED)

Zener predicted that thermoelastic losses may be a limitation to the maximum Q factor of a resonator [9]. Basically, the principle of thermoelstic damping is the following: When a mechanical structure vibrates, there are regions where compressive stress occurs and others where tensile stress occurs, in a cyclic way given by the vibration frequency. Accordingly, compressed regions heat up and stretched regions cool down. Hence a temperature gradient is established between different regions of the system. However, to set the mechanical system in vibration, energy must be provided, leading to a non-equilibrium state having an excess of energy. Disregarding thermoelastic damping, the vibration could persist indefinitely in an elastic body that is perfectly isolated from its environment. However, local temperature gradients lead to irreversible flow of heat, which is a dissipation mechanism that attenuates the vibration until complete rest is achieved. Heat flow through a thermal resistance will result in power dissipation, which is a Q limiting energy loss mechanism. This loss is the most prominent when the period of the resonator is of the same order as the thermal time constant across the beam. From a thermodynamic standpoint TED can be viewed as the initial flexing of the beam which causes the temperature profile of the beam to become more ordered. If the beam re-establishes equilibrium this order is lost, resulting in an irrecoverable increase in entropy, which is an energy loss[10].

A. The concept of the Quality factor

For a one degree of freedom mass–spring system under viscous damping, the equation of motion would be as follows [4]

$$m\ddot{x} + c\dot{x} + kx = 0$$

$$\ddot{x} + 2\zeta\omega_0\dot{x} + \omega_0^2 x = 0$$

$$\zeta = \frac{c}{2\sqrt{km}},\ \omega_0 = \sqrt{\frac{k}{m}}$$

where m is the mass, c is the viscous coefficient, x is the displacement of mass, $1/(2\zeta)$ is the quality factor of system, for $\zeta \ll 1$; ω_0 is the natural frequency of the system, and the dot sign shows the differentiation with respect to time. The quality factor of system, $1/(2\zeta)$, depends on the value of mass, viscous coefficient and spring coefficient. The free vibration response of the system may be assumed as the complex form $Xe^{i\omega}$ where X is the complex amplitude, and ω_0 is the free vibration frequency. Then by substituting $Xe^{i\omega}$ into the above equation gives

$$\omega^2 - 2\zeta\omega_0\omega i - \omega_0^2 = 0 \Rightarrow$$

$$\omega = \zeta\omega_0 i \pm \sqrt{1-\zeta^2}\omega_0 \Rightarrow$$

$$\frac{1}{2\zeta} \cong \frac{\mathrm{Re}(\omega)}{2\,\mathrm{Im}(\omega)} = Quality fac\ tor$$

B. General expressions for TED Factor (Dissipation Factor)

Consider now a resonator based on a flexural beam. When the beam bends, one side is in compression and heats up and the other is in tension and cools down. The relaxation time for the heat to travel from the hot side to the cold side depends on the thickness of the beam and on the thermal conductivity of the material. This relaxation time corresponds to a characteristic frequency. When the natural frequency of the resonator becomes comparable to this characteristic frequency maximum dissipation occurs.

Zener's solution [9] for thermo elastic damping in a thin beam can be approximated as a term Thermoelastic Damping Factor (TED Factor) or Dissipation Factor denoted as Q^{-1} which gives an idea of the internal friction in a resonator. Actually Q^{-1} is the fraction of energy dissipated per radian of vibration and can be expressed as

$$Q^{-1} = \Delta_E \frac{\omega_0\tau}{1+(\omega_0\tau)^2} \tag{5}$$

where

$$\Delta_E = \frac{E\alpha^2 T_0}{\rho C_p} \tag{6}$$

and

τ is the relaxation time determined by

$$\tau = \frac{h^2\rho C_p}{\pi^2 k} \tag{7}$$

and ω_0 is the undamped natural frequency for the relevant mode [10].

For a simply supported beam, the first natural frequency is

$$\omega_0^2 = \frac{\pi^4 E h^2}{12\rho L^4} \tag{8}$$

Lifshitz and Roukes' precise solution can be expressed in the following form [1]

$$Q^{-1} = \frac{E\alpha^2 T_0}{\rho C_p}\left(\frac{6}{\xi^2} - \frac{6\sin\xi + \sinh\xi}{\xi^2\cos\xi + \cosh\xi}\right) \tag{9}$$

where

$$\xi = h\sqrt{\frac{\omega_0 \rho C_p}{2k}} \qquad (10)$$

The symbols used in the above equations are E (Pa)-Young's modulus, α -Thermal expansion coefficient, k (W/m-K)- Thermal conductivity, C_p (J/kg-K-) Specific heat, ρ (kg/m^3)-Density, T (K)-Temperature, h (m)-Thickness and L (m)-Length.

C.Principles of Modeling of the MEMS Resonator

The modeling approach for the MEMS resonator consists of principles based on partial differential equations (PDEs) and functional relations of relevant effects in three physical domains [11]. These are the mechanical, electrical and the thermal domains. The current approach allows model parameters to be linked to actual physical and geometric parameters. Thermoelastic damping results from the coupling between the heat equation in the thermal domain and structural dynamics in the mechanical domain through thermoelastic material behaviour. TED is calculated using a complex frequency method in which it is expressed in terms of a complex resonant frequency. This approach uses the eigenvalues and eigenvectors of the uncoupled thermal and mechanical dynamics equations to calculate damping. The numerical implementation of this method has been conducted using finite element solver- COMSOL Multiphysics software-where several partial differential equations are numerically solved with complex frequency values being involved. Using a finite element formulation, a perturbation of the temperature field is explicitly applied to the governing equations associated with heat transfer, thermoelasticity, and structural vibration. This results in an eigenvalue equation with the imaginary part of the eigenvalue representing the frequency of the harmonic vibration and the real part representing the decaying rate of the amplitude [12]. The advantage of the method lies in that it is very easy to extend the same formulation to solve a problem with arbitrary geometry and complicated structures**.** Also the thermal modes that contribute most to damping can be identified and this information may be used to design devices with higher quality factors**.**

III. Simple Fixed-fixed TYPE BEAM resonators

The resonator is a beam of silicon with length 400 µm, height 12 µm, and width 20 µm as shown in Fig.1. The beam is fixed at both ends, and it vibrates in a flexural mode in the *z* direction (that is, along the smallest dimension). The model assumes that the vibration takes place in vacuum. Thus there is no transfer of heat from the free boundaries. The model also assumes that the contact boundaries are thermally insulated [8].

To gain information about the quality of the resonator, its natural frequency and Q value is investigated. For a system with damping, the eigenvalue λ contains information about the natural frequency and Q value [6]. An eigenfrequency analysis is done to find the eigenvalues for this system. Fig.2 shows the variation of TED factor with eigen frequency for a simple fixed-fixed beam resonator.. From the analysis it is clear that at some particular frequency internal friction TED factor (**Q^{-1}** or Dissipation Factor) is maximum and this corresponds to the maximum dissipation of the resonator.

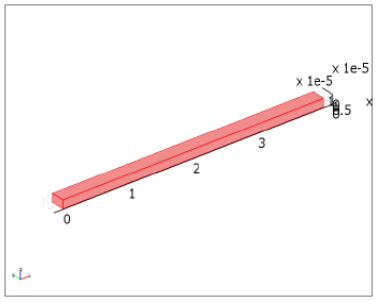

Fig. 1: Geometry of a simple fixed-fixed type beam resonator.

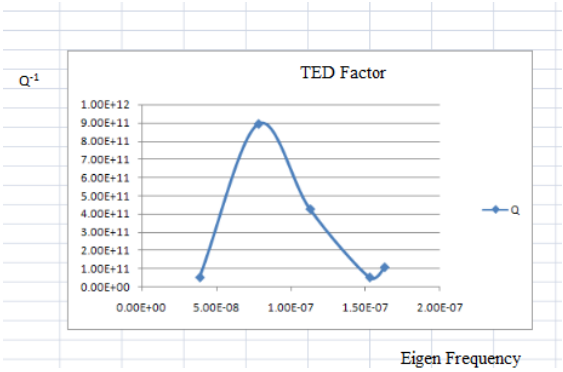

Fig. 2: TED Factor versus Eigen Frequency of a Simple fixed-fixed beam resonator.

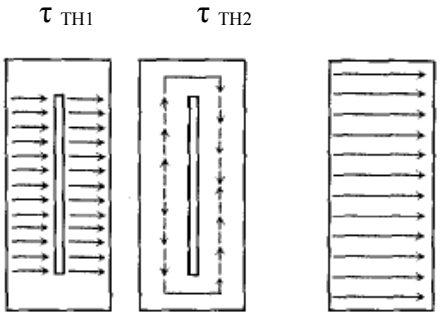
IV. Tunable Piezoelectric Actuator Based Resonators

A tunable piezoelectric actuator based resonator consists of a cantilever beam actuated by a piezoelectric device mounted on the beam as shown in Fig.3. A piezoelectric device can actuate a cantilever beam by applying an AC voltage over the device. The cantilever beam itself has resonant modes that causes peaks in the vibration when the frequency of the applied voltage matches the resonance frequency of each mode. If another piezoelectric device is attached to the cantilever, it is possible to tune the resonance by connecting that device to a passive external circuit. Piezoelectric resonators are gaining an increasing interest because of their better capacitance ratio compared with electrostatically actuated devices and for their impedances suitable for interfacing circuits [13].

Fig. 3: Geometry of a Tunable Piezoelectric Actuator Based Resonator

The piezoelectric material used is lead zirconate titanate (PZT), placed above and below the beam as shown in Fig.3 and each of the devices has two electrical connections to an external circuit, and the Q factor can be precisely tuned.The layered structure of this piezo electric actuator does not change the resonance frequency of the beam compared to a single beam of same dimension, but it affects the heat transfer across the width of the beam and hence the thermoelastic damping behaviour.



(a) (b)

Fig.4:(a)Two thermal paths exists in a tunable piezoelectric actuator (b) one thermal path in a solid homogeneous beam.

In the piezoelectric actuator based resonator as shown in Fig.4,one thermal path is across the thickness of the cantilever beam wall and the other exists around the piezostructure.τ_{TH1} and τ_{TH2} illustrate the flow of heat from hot to cool regions within the structure. The individual thermal paths have a unique frequency dependent behaviour, and we apply the principle of superposition to analyze the overall behavior. As shown in Fig.4,only one thermal path exists around a simple homogeneous beam which indicates only one peak in the analysis of TED factor.

Fig.5 shows the variation of TED Factor (Dissipation factor,$\mathbf{Q^{-1}}$) with eigen frequency for a tunable piezoelectric actuator based resonator. Dissipation factor of a resonator is directly related to its thermoelastic damping characteristics. In the present work for analysis we propose that the presence of two peaks in $\mathbf{Q^{-1}}$ indicates the possibility of two thermal paths. The multilayered structure created in a tunable piezoelectric actuator causes a discontinuity in thermal transport across the structure, altering the thermoelastic behaviour of the resonator. This can be compared with the TED characteristics of trench refilled (TR) resonators in which the thermal path is altered due to the presence of a void in the middle[14]. Here, in this work, the possibility of two thermal paths are proposed to present in a piezoelectrically actuated vibrating beam, as opposed to only one thermal path in a simple fixed-fixed type beam. One thermal path is across the thickness of the beam wall and the other exists around the piezo structure from hot to cool regions within the structure. The individual thermal paths have a unique frequency dependent behaviour, and the principle of superposition can be applied to analyze the overall behaviour. This is an average value, and actual conditions will result in broadening of the frequency dependent loss[14]**.**The corresponding relaxation time constants are τ_{TH1} and τ_{TH2} [14] and this explains the reason for two peaks in a tunable piezoelectric actuator as shown in Fig.5. The relaxation strength Δ of the two mechanisms is assumed to be equal to the relaxation strength of the homogeneous beam. Applying the principle of superposition, the overall frequency dependent quality factor of tunable piezoelectric actuator is

$$Q_{TED}^{-1} = Q_{TED1}^{-1} + Q_{TED2}^{-1} \quad (11)$$

and

$$Q_{TED}^{-1} = \Delta\left[\frac{\omega\tau_{TH1}}{1+(\omega\tau_{TH1})^2} + \frac{\omega\tau_{TH2}}{1+(\omega\tau_{TH2})^2}\right] \quad (12)$$

As shown in Fig.5,two peaks in the TED factor shows more energy dissipation within the structure of the tunable piezoelectric actuator based resonator. Even though total energy loss is high, piezoelectric resonators provide better capacitance ratio, better impedance matching and larger power handling capabilities.

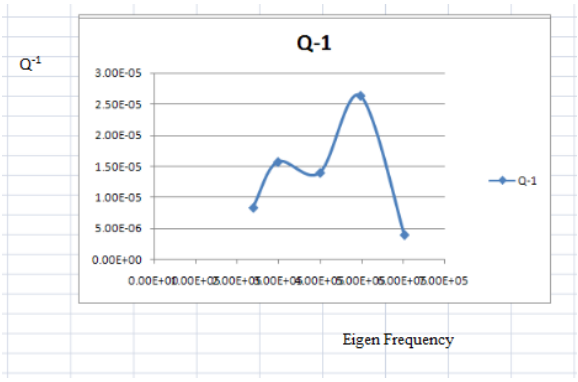


Fig. 5 :Dissipation factor (Q^{-1}) versus Eigen Frequency of a Tunable Piezoelectric Actuator Based Resonator .

Fig.6 shows the analysis of thermoelastic damping characteristics of a tunable piezo electric actuator. In the present work we propose that the presence of two minima in Q factor indicates the possibility of two thermal paths-one across the thickness of the beam wall and the other around the piezo structure from hot to cool regions within the structure. The multilayered structure

created in a tunable piezoelectric actuator causes a discontinuity in thermal transport across the structure, altering the thermoelastic behaviour of the resonator as explained above.

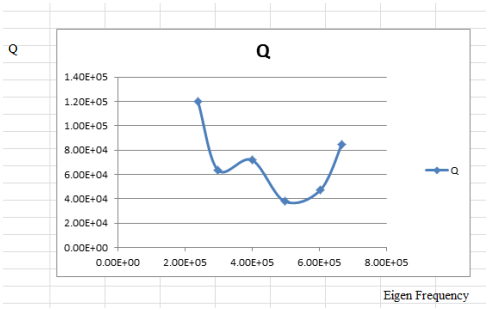

Fig. 6 :Q factor versus Eigen Frequency of a Tunable Piezoelectric Actuator Based Resonator .

Fig.7. shows the simulated output of a tunable piezoelectric actuator showing the variation of displacement along its boundary according to the colour profile given in the plot.

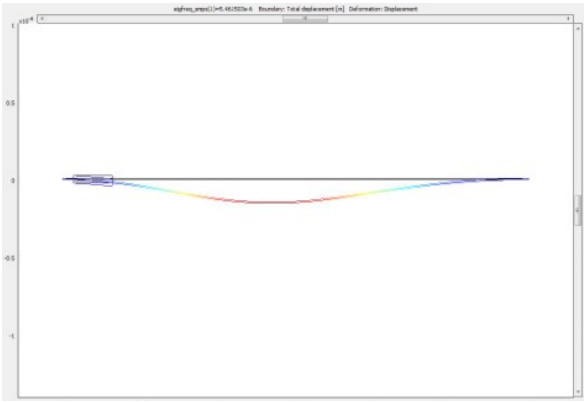

Fig.7: Simulated output of a Tunable Piezoelectric Actuator Based Resonator showing the first eigen mode and displacement.(Eigen Frequency=5.4645 MHz)

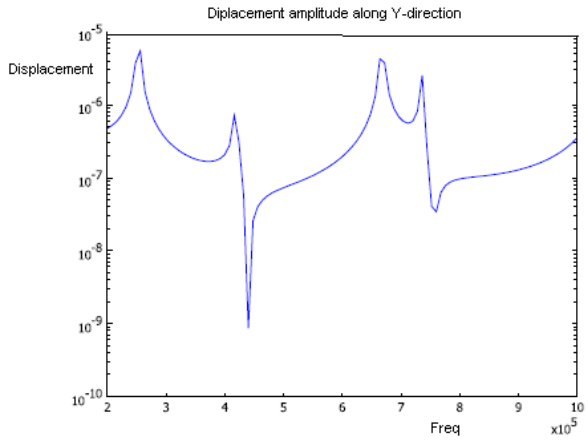

Fig.8: The amplitude of the horizontal diplacement as a function of frequency.

The analysis of the actuator is done through a frequency sweep that goes from 200KHz up to 1MHz plotting the displacement amplitude in the y-direction. As shown in the Fig.8,the vibration shows several resonance peaks .The external inductance used for this sweep is 40mH.

The spike is caused by the resonance between the capacitance of the piezoelectric device and the inductance of the external circuit. The resonant frequency for a LC circuit is

$$f = \frac{1}{\sqrt{LC}} \qquad (13)$$

Because the value for L and Freq are known, it is possible to estimate the capacitance of the piezoelectric device.

The authors acknowledge the support by National Program on Micro and Smart Systems (NPMASS) program, India.

VI. Conclusion

TED effects on a tunable piezoelectric actuator based resonator is analyzed and compared with a simple fixed-fixed type resonator. The analysis shows two minima in the Q factor corresponding to two thermal paths existing across the structure. Due to these two thermal paths the overall dissipation of the resonator increases but it shows better capacitance ratio. The analysis is done using a high end software COMSOL Multiphysics . By proper identification of the thermal modes that contribute most to damping resonators with high quality factors can be developed. Increasing the Q factor improves the signal-to-noise ratio (SNR), spectral purity, and selectivity of the system. It is therefore important to be able to predict the Q factor of a structure and have accurate design guidelines to minimize the energy losses.

stevan.preradovic@ieee.org

Abstract - A wireless sensor node based on a chipless RFID tag with integrated sensor element is presented. The chipless tag is multiresonator-based and encodes data as spectral signature. The sensor element is attached to a dedicated resonator of the chipless node. Two types of sensor elements are used – resistive and capacitive. The resistive sensor output changes the Q factor of the spiral resonator effectively changing its insertion loss at the resonant frequency. The capacitive sensor output changes the spiral resonator's resonant frequency. The chipless wireless sensor node can be used in various automated monitoring applications.

I. INTRODUCTION

In recent times Radio Frequency Identification (RFID) has slowly merged into the mainstream mainly for applications such as logistics, asset and animal tracking [1]. This is mainly due to the fact that RFID enables automated wireless data capturing of tagged objects. RFID is a wireless form of data capturing where the RFID reader (interrogator) is used to scan, detect and identify tagged objects based on the information (and or ID) provided by the RFID tag (transponder) located on the tagged object [2].

Recent advances in sensors and wireless sensor networking technologies have provided the capability to merge sensor and sensing technologies with RFID systems. Using the RFID capability of automated monitoring with sensing capabilities have increased the applications in which RFID is deployed in to those of biomedical sensing and monitoring [3], electric power monitoring [4], robot direction sensing [5], gas and temperature monitoring [6]-[7] etc.

In order to increase the further adoption of RFID, it is important to understand that one of the greatest challenges is reducing the price of the RFID tag to a fraction of a cent which is comparable to the price of the optical barcode [8]. So far the majority of the optimization process has focused on lowering the price of the RFID chip embedded with the RFID antenna [9]. Recent advances in chipless RFID development have opened a different perspective on how ultra-low cost RFID tags can be achieved. Chipless RFID tags do not comprise a silicon microchip and therefore do not require any power supply and are much cheaper to produce. This comes at the cost of using alternative methods to encode data such as time domain reflectometry, spectral signatures and backscatter phase encoding. A comprehensive overview of chipless RFID found today is presented in [10].

We have reported four generations of novel chipless RFID tags based on spiral multiresonators and orthogonally polarized ultra-wide band (UWB) monopole antennas in [11]-[14]. The multiresonator-based chipless RFID tag encodes data using spectral signature.

Previous work on integrating chipless RFID tags and sensors have been reported using SAW tags [15] and delay-lined-based tags [16]. Both tags use time-domain delays and phase difference between the tag responses to encode the sensor information.

In this article we present a novel wireless sensor node. The sensor node is as a multiresonator-based chipless RFID tag upgraded to operate as a wireless sensor node with resistive and capacitive sensors. The main differences between previously reported chipless wireless sensor nodes and the one presented in this article are: (i) data encoding is done in the frequency domain; and (ii) we present two novel sensor data encoding techniques: insertion loss amplitude/phase variation and resonant frequency variation. The novel chipless wireless sensor node proto-type is planar and printable, has zero power consumption and can withstand higher temperatures than chipped RFID tags since there are no silicon circuits in the tag.

II. DESIGN

The schematic of the chipless wireless sensor node on Taconic TLX-0 (ε_r=2.45, h=0.787mm, tanδ=0.0019) is shown in Fig. 1.

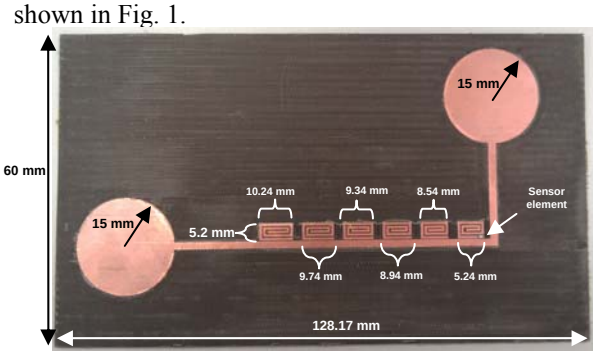

Fig. 1 Layout and dimensions of chipless wireless sensor node.

The sensor node is developed in microstrip technology. It consists of a vertically polarized UWB disc loaded monopole receiving antenna, a multiresonating circuit and a horizontally polarized UWB transmitting antenna. The receiving and transmitting sensor antennas are cross-

polarized in order to minimize interference between the interrogation signal and the re-transmitted encoded signal containing the spectral signature.

III. SENSOR DATA ENCODING SCHEME

The chipless wireless sensor node encodes data into the spectrum using spiral resonators with a 1:1 data bit correspondence (*n bits = n spirals)*. A spiral resonator coupled to the microstrip line creates a stop-band resonance and therefore can be modeled as a parallel RLC circuit. The values of the R and C are varied with sensor element outputs in order to encode data.

The integrated sensor element is placed at the end of the spiral resonator operating at the highest frequency (spiral length = 5.24 mm) as shown in Fig. 2. Two different sensors are integrated in the sensor node: resistive and capacitive. The effects of these sensors and data encoding of the sensor outputs are presented in the following subsections.

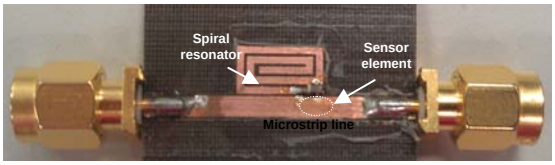

Fig. 2 Integration of element on spiral resonator

A. *Resistive Sensor*

The performance of the spiral resonator as a stop band filter is determined by two factors: resonant frequency and Quality (Q) factor. When using a sensor element which has a sensor output in the form of real impedance (resistance) the Q factor is influenced. This is obvious from equation (1):

$$Q = \frac{\omega L}{R} \tag{1}$$

where Q is the quality factor, L is the spiral inductance, R is the spiral resistance and ω is the angular resonant frequency at frequency f defined as:

$$\omega = 2\pi f \tag{2}$$

From (1) it is clear that the increase in R will mean that the Q will reduce (and vice versa) and effectively the insertion loss of the spiral resonator at the resonant frequency will also drop as shown in Fig. 3. A sensor element in the form of a thermistor can be used for temperature monitoring.

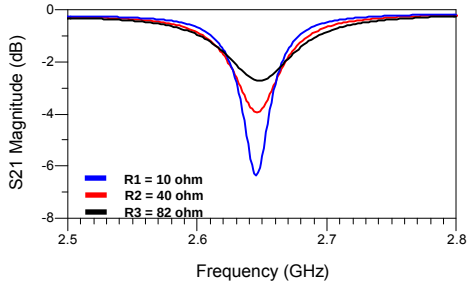

Fig. 3 Variation of spiral resonator's insertion loss with sensor resistance *R*.

B. *Capacitive Sensor*

When using a sensor element which has a sensor output in the form of capacitance the resonant frequency is influenced.

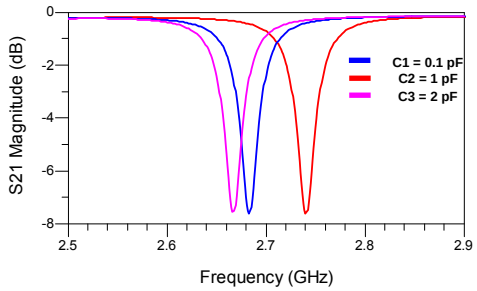

Fig. 4 Variation of spiral resonator's resonant frequency with sensor capacitance *C*.

This is obvious from equation (3):

$$f_r = \frac{1}{2\pi\sqrt{LC_e}} \tag{3}$$

,where fr is the resonant frequency, L is the spiral inductance, Ce is the equivalent capacitance of the spiral resonator and sensor element and L is the spiral inductance.

From (3) it is clear that the change in C will mean that the spiral's resonant frequency will change with negligible influence to the insertion loss as shown in Fig. 4.

IV. RESULTS

In this section we present the measured results of the wireless sensor node consisting of the chipless tag and integrated resisitve and capacitive sensor elements separately. The design of the wireless sensor node was done in microstrip technology on Taconic TLX-0 laminate using Agilent ADS 2008 software (Momentum and Transient Co-Simulation).

A. *Multiresonator with Resistive Sensor*

Figs 5 and 6 show the response of the chipless wireless sensor node multiresonator circuit with an integrated sensor element on the smallest spiral resonator in magnitude and phase respectively. This results in the highest resonant frequency being reserved for sensor data encoding.

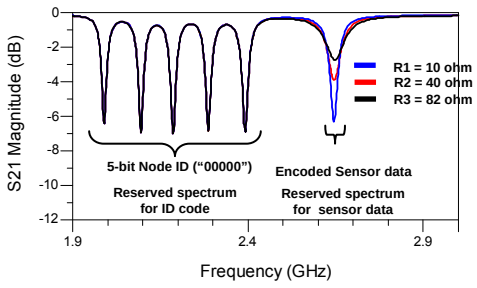

Fig. 5 Measured s-21 magnitude response of chipless sensor node multiresonator circuit with integrated resistive sensor.

From Fig. 5 it is clear that the insertion loss varies for different values of sensor resistance. The higher the resistance the smaller the Q factor is as expected. The same occurs in the s21 transmission phase response shown in Fig. 6 where the transmission phase jumps vary with the variation of resistive sensor output. The advantage of this type of sensor data encoding is that the additional spectrum is not required. The disadvantage of this type of sensor encoding is that it might be difficult to detect smaller variations of the spiral resonator's insertion loss.

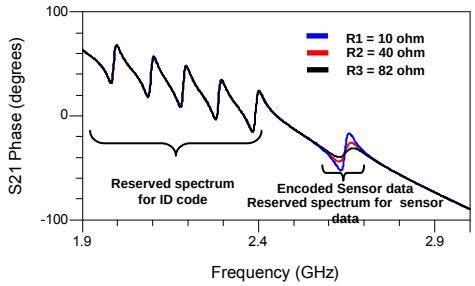

Fig. 6 Measured s-21 phase response of chipless sensor node multiresonator circuit with integrated resistive sensor.

B. *Multiresonator with Capacitive Sensor*

Figs 7 and 8 show the response of the chipless wireless sensor node multiresonator circuit with an integrated capacitive sensor element on the smallest spiral resonator in both magnitude and phase respectively. From Figs 7 and 8 it is clear that the spiral resonator's resonant frequency varies for different values of sensor capacitance as expected. The resonant frequency can be observed in both magnitude and phase where phase detection can be used for more robust reading. The advantage of this type of sensor data encoding is that it is easier to detect than insertion loss variation. The disadvantage of this type of sensor encoding is that it requires additional spectrum for data encoding.

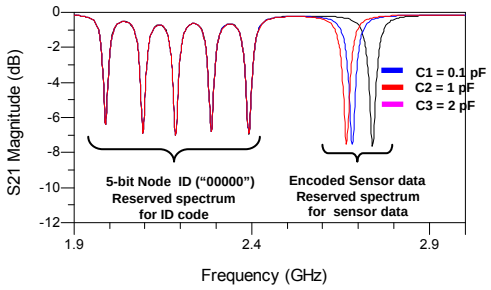

Fig. 7 Measured s-21 magnitude response of chipless sensor node multiresonator circuit with integrated capacitive sensor.

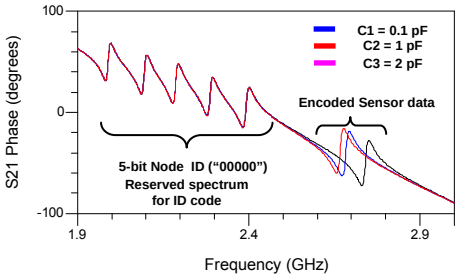

Fig. 8 Measured s-21 phase response of chipless sensor node multiresonator circuit with integrated capacitive sensor.

C. *Interrogation of Chipless Wireless Sensor Node*

In order to test the designed chipless wireless sensor node we assembled a measurement setup shown in Fig. 9. The wireless sensor node was mounted on a plastic jig inside an anechoic chamber and read at a distance of 10 cm with log periodic dipole antennas (LPDA) as reader antennas.

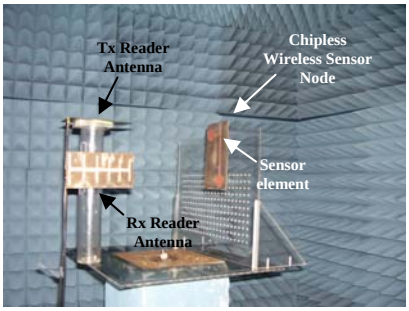

Fig. 9 Measurement setup for testing the chipless wireless sensor node with integrated sensor element.

The measurement setup comprised cross-polarized transmitting (Tx) and receiving (Rx) reader antennas and the chipless wireless sensor node. The reader transmitted a frequency swept continuous wave (CW) signal from 1.9 – 2.9 GHz at 0 dBm power. The reader antennas were cross-polarized in order to isolate the transmitted interrogation signal from the received sensor node signal comprising the sensor node ID and sensor data in the form of a spectral signature.

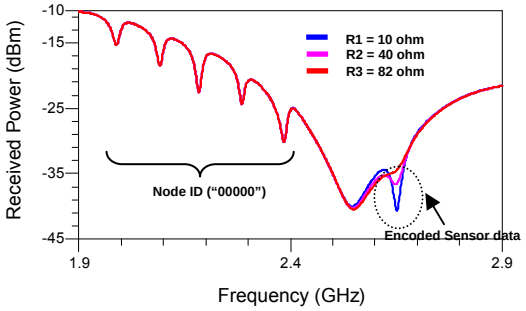

Fig. 10. Spectrum magnitudes of 3 measured responses of chipless wireless sensor node for different sensor outputs *R*.

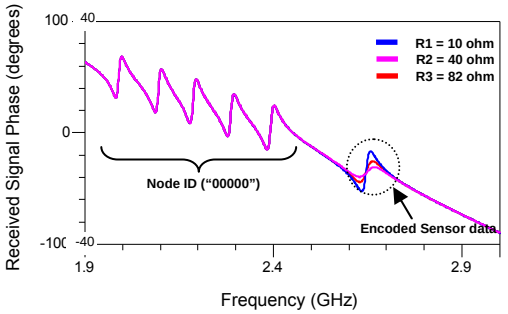

Fig. 11. Spectrum phases of 3 measured responses of chipless wireless sensor node for different sensor outputs *R*.

Figs 10 and 11 show the measured results of the wireless interrogation system shown in Fig. 9 with a resistive sensor element. Three different sensor outputs

were measured but this time the multiresonator circuit was embedded into the wireless node and detection of the sensor node was performed using Agilent's PNA E8361A. From Fig. 10 it is clear that the sensor node ID which was set to "00000" was correctly detected but also the variations of the insertion loss at around 2.55 GHz where the sensor data was encoded. Three different sensor outputs were set with *R* having the value as in Figs 5 and 6. Fig 11 shows the normalized received signal phase for 3 different sensor outputs. The received signal phase was normalized using a wireless sensor node response with 11111 ID (no resonances) and *R =1K* as a reference so that 'jumps' in the phase are detected.

Figs 12 and 13 show the measured results of the wireless interrogation when three different capacitive sensor outputs are present on the wireless sensor node. From Fig. 12 it is clear that the wireless sensor node ID which was set to "00000" was successfully detected but also the frequency shift of the 6th spiral's resonant frequency for different capacitive sensor outputs. Fig. 13 shows the normalized phase response of the received signal from the wireless sensor node. The same reference tag was used for this measurement as mentioned in the previous paragraph. This measured results confirmed the successful operation of the chipless wireless sensor node and sensor data encoding using capacitive sensor. Three different sensor outputs were set with *C* having the value as in Figs 7 and 8.

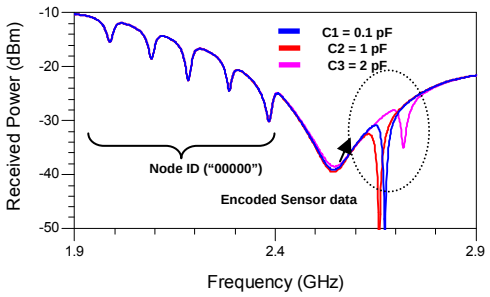

Fig. 12. Three measured response of chipless wireless sensor node with integrated capacitive sensor element with 3 different sensor outputs.

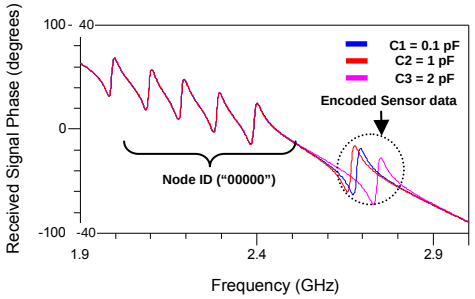

Fig. 13. Three measured response of chipless wireless sensor node with integrated capacitive sensor element with 3 different sensor outputs.

V. CONCLUSION

In this article we have presented a fully printable chipless wireless sensor node with integrated sensor elements. Two sensor elements with resistive and capacitive sensor outputs were integrated on a dedicated spiral resonator to encode the sensor data. Other spiral resonator's are used to encode the ID of the chipless wireless sensor node for identification purposes. The measured results in this manuscript have confirmed the successful operation of the chipless wireless sensor node where the wireless sensor node ID with encoded sensor data was detected using Agilent's PNA as a RFID reader. The wireless sensor node proves the concept and renders the wireless sensor node operational. Future research should focus on investigating the maximum reading ranges for both cases of sensor data encoding and mitigating towards fully printable sensor elements.

The wireless sensor node based on the chipless RFID tag has great potential for low-cost sensing applications.

zivorad@uns.ac.rs

Abstract – This paper describes hardware system for monitoring gas migration inside of borehole wells on landfill site. Hardware unit is designed to show the applicability of such device in terrain conditions. Therefore, we used easily available and cheap sensors for gases such as nitrogen dioxide and carbon monoxide. The solution can easily be expanded with other types of gas sensors, if necessary. Temperature and humidity sensors are installed for the measurement compensation that depends on these parameters. The device includes GPRS/GPS modem that allows sending data to server application for further processing. Also, the control of device via server application and SMS service has been implemented. Integration of microcontroller inside sensor system allows implementation of automatic monitoring and support for management of the outer actuators and alarms. Simple client application displays the results of measurements in real time, if necessary, or in the adjustable time intervals, which is useful for battery supplied operation.

I. INTRODUCTION

Today, numerous efforts are made to preserve the environment such as ecological production, usage of renewable energy and recycling. Greenhouse effect, which occurs due to greenhouse gas emissions, affects global warming which could lead to climate changes in the geologically short period of time. Landfills have significant influence on the total gas emissions and therefore should have monitoring and management to reduce pollution to a minimum. However, over the past decades standards and practices have been steadily improving and many new technologies have been adapted or specifically designed to control and monitor the processes within a landfill [1].

Modern landfills are engineered sites, designed to efficiently contain municipal solid waste while collecting the produced landfill gas. Gas collection systems operate continuously, usually consisting of vertical wells and sometimes horizontal trenches or other zones filled with permeable material within the waste, from which landfill gas is extracted by application of a vacuum. General tendency is to use gas emissions from the landfill as an energy source (natural gas) [2] or burn and convert it into harmless compounds. It is important to know concentration of gases at all times, for achieving better efficiency. Possible hazardous situations must be detected promptly and system must have a way to respond to such situations.

In this paper one such system is presented. Microcontroller based system measures the concentration of NO_2 and CO gases and makes decisions in accordance with the requirements. The collected data are sent via GPRS (General Pocket Radio Service) to server applications, and controls are also available in a different direction or via SMS (Short Message System) support. The server application shows the parameters of interest in real time.

II. LANDFILL GAS EMISSION

Landfill gas is produced by the decomposition of organic waste in an anaerobic environment. The main constituents of landfill gas and their proportions are captured in Table 1. These values can vary from landfill to landfill, but generally the main components of landfill gas are the greenhouse gases, methane (CH_4) and carbon dioxide (CO_2).

TABLE I. VARIATIONS IN LANDFILL CONCENTRATION [4*]

Constituent Gas	Concentration (by volume)	
	Range	Average
Methane (CH4)	35 – 60 %	50 %
Carbon Dioxide (CO2)	35 - 55 %	45 %
Nitrogen (N2)	0 – 20 %	5 %
Oxygen (O2)	0 – 2,5 %	< 1%
Hydrogen Sulfide (H_2S)	1 – 1700 ppm	21 ppm
Halides	NA	132 ppm
Water Vapor (H_2O)	1 – 10 %	NA
Non Methane Organic Compounds (NMOCs)	237 – 14,249 ppm	2700 ppm

It is observed that the main components of landfill gas are methane and carbon dioxide. The fact that methane is about 20 times more harmful to the environment than carbon dioxide justifies the efforts to control gas emissions [3]. Thus, it is desirable that landfill site has installed system for gas collection in order to decrease influence on environment, whether the gas is used as fuel, or just burned. Methane (or similar hydrocarbons) mixed with some gases, especially with oxygen, can create explosive mixture. Other landfill gas constituents, such as non-methane organic compounds (NMOCs), can contribute to smog formation while others, such as hydrogen sulfide (H_2S) and halides, pose health hazards due to their toxicity.

Today there are a lot of engineering methods to construct a landfill. The infrastructure is specifically

designed to allow extraction of gas and its use as a fuel rather than flaring. Fig. 1 shows the cross section of the landfill. Structure is layered and designed to reduce impact on the surrounding of landfill and vice versa. A special attention is paid to avoid possible contamination of groundwater. Gas collection system needs to penetrate all the layers wherelandfill gas is generated.

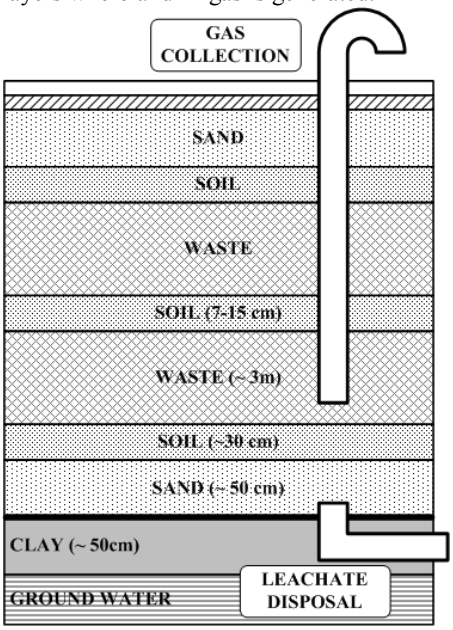

Figure 1. Typical construction of the landfill site with gas collection system

A few decades ago landfill sites were not designed for gas extraction and design process was not perfected as today. In these landfills, it is not possible to predict amount of gas that is produced. Today, on modern landfills it is possible to predict the methane generation rate [4].

Efforts have been made to exploit old landfills as fuel sources as well. There are many factors that influence the emissions on these landfills. A drop in atmospheric pressure can lead to an increase in the amount of gas vented from the landfill. The soil type where the landfill site is situated is of great importance for monitoring gas emissions. Areas near peat or coal soils can have background CH_4 content in the soil [5]. The moisture content of the landfill is also an important factor. If the surface soils and clay capping are waterlogged, the flow of gas will not be able to reach the surface and this will decrease the amount of emitted landfill gas.

The age of the landfill also results in changes of landfill emissions rate. Generation of landfill gas begins 3–12 months after deposition of the waste in the landfill. It usually continues for 20–50 years, once the landfill had been closed, though some traces of landfill gas production can be generated for up to 100 years depending on the rate of degradation and gas production and extraction. The older the landfill, the more gas emissions will fluctuate. This results from the fact that the older sites did not have gas management and recovery systems were placed in before waste deposition began. The sites are retrofitted and, therefore, not as effective.

Currently on the market there are several commercial devices that are mobile and generally require labor in the field. Stationary devices are now largely in the prototype versions, but the results are promising [6]. Problems with stationary devices are theft of equipment, and the necessity of designing low power consumption system.

Considering the above, it can be concluded that process of landfill gas generation can be unpredictable. The optimal exploitation requires the installation of systems for real time monitoring and remote control. Ideally, each borehole should include a unit for monitoring, but it is also satisfactory if the measurement is performed at certain nodes of the pipeline. This paper shows that remote unit for monitoring and control can be implemented.

III. IMPLEMENTATION OF SYSTEM

The main requirements to be met by the unit include: measurement of gas concentration, data processing inside microcontroller, minimal power consumption, two-way wireless data transfer, processing and displaying data on a server and real time execution.

Implemented system contains gas sensors that were available at the moment of system design. The metal-semiconductor sensors for CO (Figaro TGS2442) and NO_2 (e2v MiCS-2710) were used. However, the unit can easily be modified byinstallingrequired sensors.

For wireless communication Telit's GM862-GPS GPRS modem is used. It is possible to adjust the modes of operation and control of sending data via serial communication. Modem supports sending GPS coordinates which can be used to identify borehole positions and graphic representation in application.

Whole system consists of hardware and software parts that will be explained in more detail.

A. Hardware design

Designed hardware is physically composed of three modules: power supply, microcontroller and sensor boards (Fig. 2).

Since the device should work under field conditions, a power supply that has a minimum consumption in sleep mode was designed. In this way is achieved consumption about 1 mA in sleep mode, so that a 12 Ah (6 V) lead battery lasts about 2 months, depending on frequency of sending data. Average consumption in full operating mode is 150 to 200 mA, depending on signal strength of mobile networks. It should be noted that Telit GPRS modem can have current bursts up to 2 A when sending data. A linear regulator in a chip form (Linear Technology LT1763 5 V) and high capacitance electrolytic capacitors allow proper operation at high current peaks. Total time of sending data (wake-up, configuration of modem and connection to network, opening socket and sending data) is less than 30 seconds. After this time device goes to sleep mode. Data sending frequency influences on power consumption. For example, if data are sent once in every 15 minutes,

consumption will be about 46% of above mentioned battery power per month. There is no information about optimum frequency of data sending at the moment. Battery source can be replaced or recharged by alternative energy sources such as solar panel. All components are able to withstand harsh environmental conditions.

Management of the whole device is performed by microcontroller dsPIC30F4013. This microcontroller (MCU) is powerful enough to deal with real time execution and contains many different peripherals for connecting with external devices. MCU via RS232 serial communication exchanges data with a modem and reads the GPS position.

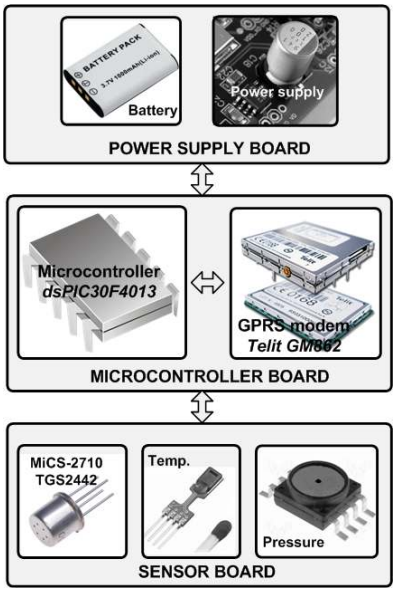

Figure 2. Hardware blocks of system for landfill monitoring

GPRS modem is responsible for sending data to remote server machine, and reception of remote commands. MCU packs sensor results in predefined format and sends data to server via GPRS. Also, server can send commands to control or configure measurement unit. Telit's GM862 module supports quad band GPRS, application in wide temperature range, low power consumption in idle mode, control via AT commands (AT - Attention in Hayes command set) with integrated TCP/IP stack. MCU sends AT command as a string of characters through serial interface. Since the modem works on the operating voltage of 3.3 V, a voltage level converter is made.

Set of gas sensors with signal processing logic is placed on third printed circuit board (PCB) which is connected to main board containing MCU. These sensors can be different depending on supply voltage and output logic. That is the reason for placing sensory part on separate PCB. Each sensor uses filtered power supply and has a special circuit that adapts the signal to MCU. Part of signal conditioning is programmable amplification of output signal from sensor. It is not recommended that all sensors work at the same time, since some of them can consume tens of milliamps during normal operation. This ensures that the power supply is smaller in dimensions and economically acceptable. Each sensor has a switching circuit controlled by a microcontroller as it is shown on Fig. 3.

Carbon-monoxide gas sensor TGS2442 has output resistance dependent on the concentration of gas. Its normal operation requires a special way of management by MCU. Typical detection range is from 30 to 1000ppm.

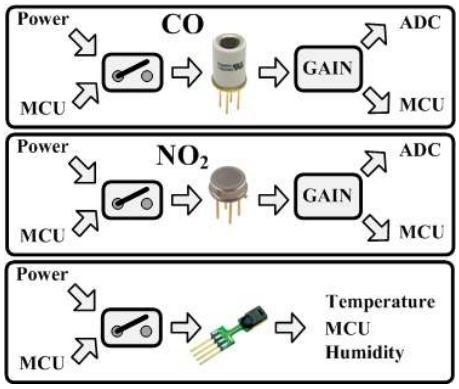

Figure 3. Block diagram of sensor circuit board. MCU controls the power and gain. Outputs are connected to analog-to-digital converter of MCU.

Sensor for NO_2 is metal oxide semiconductor e2v MiCS-2710 which offers low heater current, wide detection range (from 0.05 to 5ppm), high sensitivity, fast thermal response and miniature dimensions. Since the sensor requires 1.8 V heater voltage, special power supply is made. These sensors use heating to eliminate environmental influences, but impact of temperature, humidity and pressure cannot be always ignored. Therefore, the designed board includes sensor SHT71 for measuring temperature and humidity and MPXAZ6115A sensor for pressure measurement. Using temperature, humidity and atmospheric pressure data, server application can correct readings from gas sensors. Implementation of the final device is shown in Fig. 4.

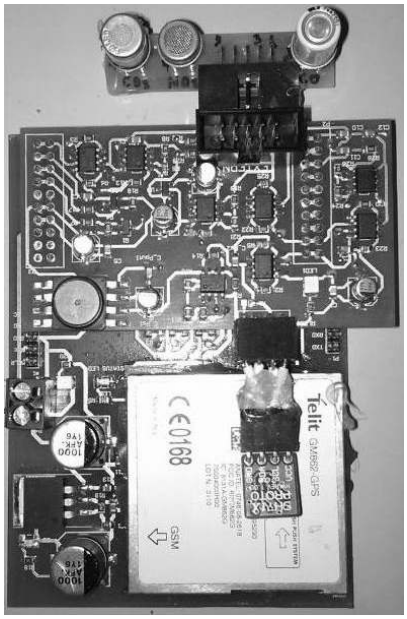

Figure 4. Prototype hardware implementation of system for monitoring landfills

B. *Software design*

As already noted, the dsPIC30F4013 microcontroller is responsible for the proper functioning of the unit. Special functions are implemented to manage AD conversion, power management and communication with the GPRS modem. CO and NO_2 sensors require very precise timings for proper operation. This is why readouts of these two sensors are done through interrupt routine. This ensures that all manufacturer recommendations are fulfilled so we have correct results and lifetime of sensors. Temperature and humidity sensor is connected to MCU via serial interface and its readout is done in main function.

Telit GPRS modem contains two UART ports, one for duplex communication with MCU and second for GPS reading. Due to power supply constraints, designed system has several working modes. The most demanding normal mode is the least used and duration of this mode affects on battery life. Normal mode includes wakening up of device, activation of sensors, reading data and sending data via modem. After normal working mode, device enters the sleep mode and remains in this mode until the next measurement or reception of special request from server. After initialization, which includes gain adjustment for sensors, initialization of SHT71 interface, the opening and testing of modem connection and processing data from server if any, measurement begins.

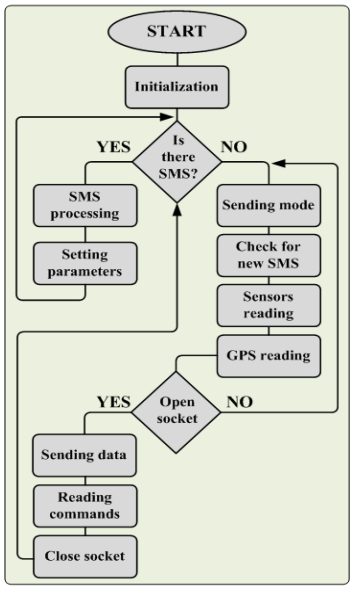

Figure 5. Algorithm of data sending via Telit GPRS modem

An SMS support is also implemented. Operator can send configuration parameters at any time. The operator can send specific parameters via SMS if there is a problem with a server application. If there is a problem with the server, the data can be redirected to another server by sending an SMS message. Fig. 5 shows algorithm for data sending via GPRS modem.

After sending data, the unit goes into sleep mode with minimum power consumption. From this state unit can be awakened with the commands from server, with SMS or when next measurement cycle starts. Received data are processed and displayed on the server application (Fig. 6).

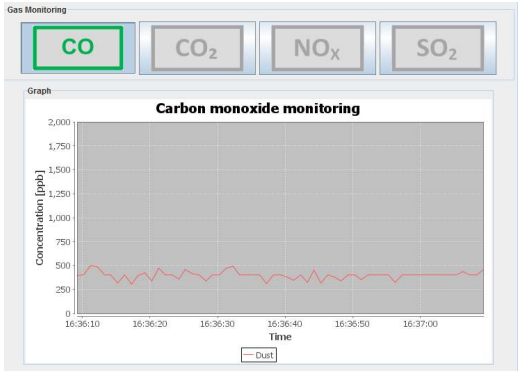

Figure 6. Server application written in Java for data visualization

IV. Conclusion and Future Work

Bearing in mind that the landfill sites can be sources of pollution and lead to greenhouse effect, there is a need for systems for real time monitoring of processes inside borehole. This paper presented one solution that has advanced features such as, low power consumption, sending data in real time, miniature and modular design, self diagnostics and reliability. Tests have shown that this data collection method may in the future replace the old methods, such as the measurement of gases with handheld devices.

Abstract - In this paper, we developed and positively tested the effective gas safety management system using wireless intelligent gas safety appliances to monitor gas flow and pressure, earthquake in a micom-gas-meter, to check combustible gas leaks and temperature (upper 100℃) in an automatic extinguisher and to detect smoke and CO gases. Then our system take safety measures such as cutoff, warning and messaging to protect a serious risk if results of event are abnormal, communicate with a wall-pad including a gateway with Jennic ZigBee network in buildings and inform those risky events to user via the safety management program in our web server. Also, the built-in every inner cutoff valve in intelligent gas meters and the middle valves in automatic extinguishers are operated automatically if irregular events are occurred and signal to the controlling wall-pads to a managing server.

I. INTRODUCTION

The new and excellent class apartments are equipped with safety devices in parts of gas, electricity and water facilities. It is clear that sensors will be made of safer and more comfortable human lives in the future. We can use them as not only fire alarms or gas leak detectors, but also biochemical attack watchers [1].

We propose a gas safety management system by using intelligent multi-function gas meters, which include ZigBee network technology, automatic gas leak cutoff, sensors of smoke, methane and temperature.

At first we developed the intelligent micom-gas-meter which has a built-in cutoff valve and sensors of flow, pressure and earthquake [2, 8]. That gas meter operates its inner valve and shut off the gas, serving a warning on users if any abnormal event is occurred for the gas flow, pressure and earthquake.

Also, external gas valve in the automatic fire extinguisher is cut off if they are to monitor temperature of upper 100 ℃, smoke for fire and leakage of methane and CO in gas pipeline and facilities [3].

In this paper, we equip wireless modules to gas safety appliances. Those are EM250 ZigBee chips with ZigBee PRO stack [4-7]. A proposed gas safety management system is configured by the topology of star types with a micom-gas-meter, an automatic extinguisher with a methane detector and a temperature sensor, and two sensors of smoke and CO [8]. And then controls all the gas safety devices through a wall-pad including a gateway with ZigBee network. If abnormal state is occurred at every sensor, the system takes safety measures to protect a serious risk [9]. And the system inform risk situation of user. But, those system were happened some problems on wireless communication. So we improved the performance of gas safety Gas safety management system using Jennic 5139 ZigBee chips by adding functions of remote control via web sites and upgrading performance of wireless communication and structure.

II. THE INTELLIGENT GAS SAFETY APPLIANCES

A. *The intelligent Micom-gas-meter*

The intelligent micom-gas-meter, a kind of a general gas meter, built in a micro-controller and a cutoff valve, is not only to measure gas flow and pressure but also to monitor earthquake. This instrument can open and close an inner cutoff valve and serve a warning on users if it is uncommon for flow, pressure and earthquake in gas facilities and houses [2]. Fig. 1 shows the appearance of an intelligent micom-gas-meter with a wireless ZigBee communication module(cyan color) including JN5139.

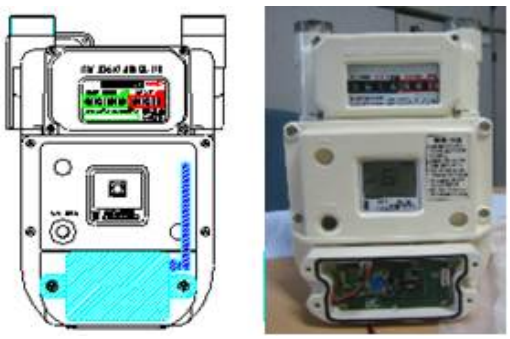

Figure 1. Micom-gas-meters with wireless modules

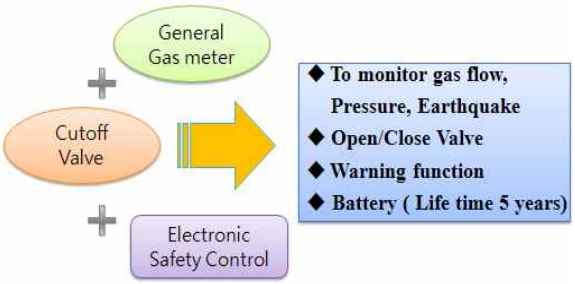

Figure 2. Components and functions of an intelligent micom-gas-meter

In Fig. 2, the components and functions of an intelligent in micom-gas-meter are showed. The micom-gas-meter consists of a general mechanic type gas meter pulus a built-in cutoff valve and electronic safety functions, which measure flow rate of gas, pressure, and earthquake. Flow types are massive, cumulative, instantaneous rising and descending items. Pressure types are mainly high and low pressure components. An earthquake measuring 3.0 on the Richter Scale and alarming, and buzzer functions [2]. Table 1 appears safety functions which a micom-gas-meter can intelligently control itself.

TABLE I. FUNCTIONS OF AN INTELLIGENT MICOM-GAS-METER

No.	Functions
1	The mass flow rate (m^3/h)
2	The cumulative flow rate (m^3/h)
3	The instantaneous rising flow rate (m^3/h)
4	The instantaneous descending flow rate(m^3/h)
5	The detail flow rate (m^3/h)
6	Set of higher pressure (mmH_2O)
7	Set of lower pressure (mmH_2O)
8	The continuous use time (min)
9	Open/Close cutoff valve
10	Check cutoff valve
11	Management codes, Alarming and buzzer

B. *The Automatic Fire Extinguisher(APE)*

Fig. 3 shows the receiver of APE with a ZigBee module. Fig. 4 shows the connected configuration of an automatic fire extinguisher set to operate. The receiver of an automatic fire extinguisher with a wireless ZigBee module makes a shut off valve close if any risk signal is received from signals of a gas leak detector and a temperature sensor indicating 100˚C. And that receiver makes a fire extinguisher operate to spray fire-extinguishing chemicals when a measuring temperature of sensor is reached at 130˚C and maintained for about 1 minute afterward 100˚C state. The gas leak detector output 12V when to detect combustible gas.

Figure 3. The receiver of APE with a ZigBee module

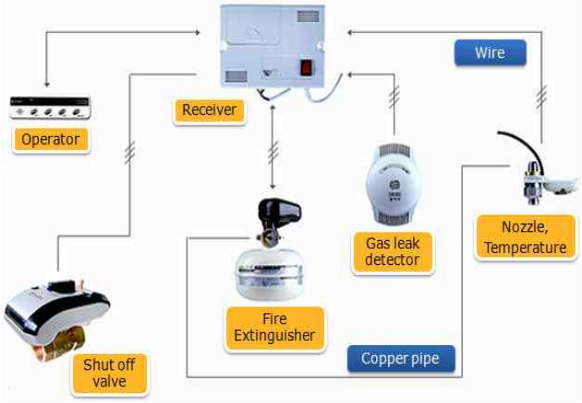

Figure 4. The configuration of an automatic fire extinguisher

C. *The smoke and CO sensors*

Fig. 5 shows a smoke and a carbon monoxide(CO) sensors. They are directly connected with a wall-pad as Fig. 6. In here, a smoke sensor with a wireless ZigBee module sends out an event signal to a wall-pad via the receiver of automatic fire extinguisher when smokes are occurred. A CO sensor with a wireless ZigBee module sends out to a wall-pad via risk signal to a wall-pad via the receiver of automatic fire extinguisher when CO gases are detected.

Figure 5. A CO & smoke sensors with ZigBee modules

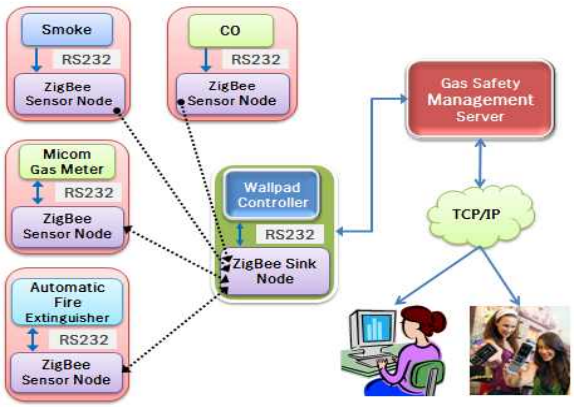

Figure 6. The inner protocol of the gas safety management system

D. *The wireless ZigBee modularization*

Fig. 7 shows our manufactured wireless ZigBee modules using JN5139. ZigBee modules are equipped with gas safety appliances, such as the micom-gas-meter, an automatic extinguisher and sensors of smoke and CO. As Fig. 6 the inner protocol of network configuration and flow stream of signals are described to operate gas safety management system. To configure ZigBee sensor network,

we used JN5139 ZigBee devices and ZigBee PRO stack [6, 7]. We used a wall-pad, which is specifications with an IEC266 (32bits RISC ARM920T, 64MB RAM and NAND Flash). Fig. 8 shows a wall-pad and gas safety appliances.

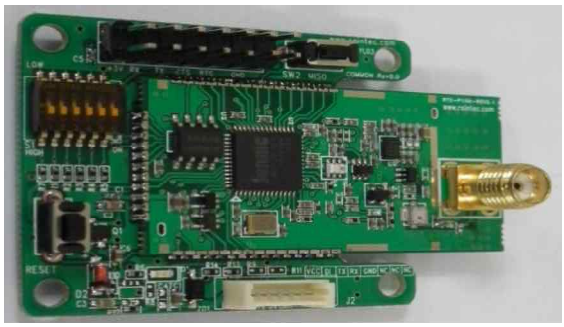

Figure 7. Our manufactured ZigBee module with JN5139

Figure 8. A wall-pad and gas safety appliances with ZigBees

III. THE GAS SAFETY MANAGEMENT SYSTEM

Table 2 shows communication protocols and baud rates on inter-connection between gas appliances and ZigBee modules.

TABLE 1. BAUD RATES OF INTER-DEVICES AND NODES

Node	Wired-Protocol
Sensor node ↔ Micom Gas meter	RS-232, 4,800 bps
Sink node↔ Wall-pad	RS-485, 9,600bps, Half-duplex
Wall pad↔ USB port	RS-232, 38,400bps
Wallpad ↔ gas safety server	Ethernet 10Mbps

Fig. 9 shows our gas safety management system(GSMS) using wired and wireless integrated communication. We configured ZigBee communication network in the buildings and BcN out of the building to operate wired and wireless integrated gas safety management system. In wireless sensor network, nodes are configured of a sink node and 4 sensor nodes. A sink node is a wall-pad with a ZigBee communication. Sensor nodes are a micom-gas-meter, an automatic fire-extinguisher, smoke detector and a CO sensor. A wall-pad controller is in the center of a ubiquitous sensor network every house. ZigBee ubiquitous sensor network is used as the star topology in one house [5, 6] and all gas safety appliances can be controlled by a wall-pad with function of wireless gateway. And a wall-pad can connect sensor nodes and our gas safety management server through LAN or wireless LAN. That server is connected to the Broadband Communication Network (BCN) in management office. In Fig. 8 Line and dotted line are the connection of wired communication and wireless ZigBee network, respectively. Web server used a ML350G6 HP Server with the Xeon Processor E5504, MS Windows7 OS, and MS SQL 2008.

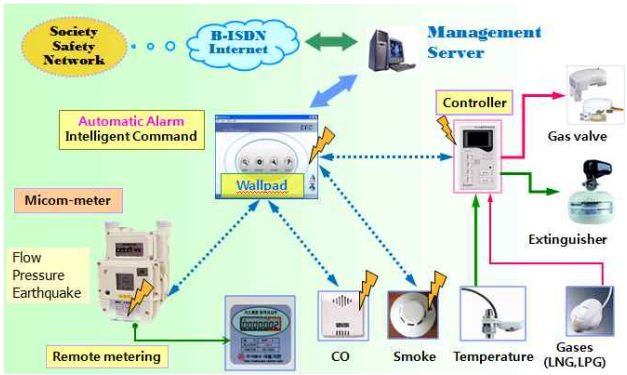

Figure 9. The configuration of Gas Safety Management Service

TABLE 2. GAS SAFETY MANAGEMENT SCENARIO

N	Appliances	Safety Procedure
1	A micom-gas-meter	- Structure : built-in sensors(a pressure, a flow rate, a seism scope, and an inner gas valve) - Monitoring : gas pressure, flow rate and an earthquake - Operating : alarm, shut-off valve
2	A automatic fire extinguisher	- Monitoring : LNG/LPG gas leak detection and temperature(100 &130℃) - Operating : alarm, shut-off of an external gas valve for gas leak and above100 ℃ and close an inner valve in micom-gas-meter, then spray fire-extinguishing chemicals in case of above 130 ℃, and open curtain and windows, activate a fan
3	A smoke sensor	- Monitoring : smoke - Operating : alarm, close an inner valve in a micom-gas-meter and then stop a boiler system
4	A CO sensor	-Monitoring : carbon monoxide gas -Operating : alarm, open curtain and windows, activate a fan, close an inner valve in a micom-gas-meter, and then stop a boiler system

Users are able to connect to sever via internet network (BcN) and to check the states of a micom-gas-meter, an automatic fire extinguisher, a CO and a smoke sensors in every house. The states of detailed functions of gas safety appliances are checked, such as open/close of an inner valve, values of pressure and earthquake in a micom-gas-meter, a smoke detector and a CO sensor. Mechanisms of all gas safety appliances are intelligently operated by inner firmware according to the procedure of our safety

management scenario as table 2 when a risk event is occurred. And then those warnings are transmitted to users and managers via home gateway to server. As Fig. 10 users can verify gas safety conditions and remotely control gas safety appliances in their home through wireless internet(WWW) using a mobile IT instrument or PC. We can monitor flow rate, pressure, earthquake, LNG/LPG leakages, temperatures of 100˚C and 130˚C, smoke and CO using our gas safety management system as Fig. 11, a web page screen to control and manage gas appliances and system on the internet at remote distances. Our system can protect gaseous risks exploration and risks and reduce range of damage.

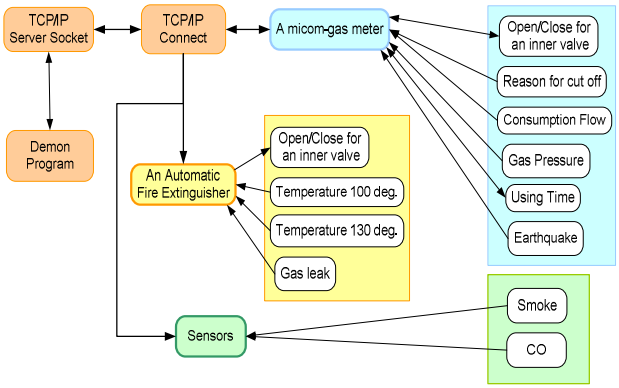

Figure 10. Configuration to connect web of GSMS

Figure 11. The Screen of Web Service of GSMS

Fig. 12 shows a test bed to experiment our Gas Safety Management System to operate a variety of conditions. We fixed and assembled our gas safety appliances on the panel similar to real conditions. We tested performance of GSMS according to table 2 gas safety management procedure. In Fig. 13, two types of experimental data for flow rates are showed. First shows state of cumulative flows is when flow rate exceeds an installed limit in a gas-meter in advance. Second is when the instantaneous rising flow rate can be abruptly occurred if gas pipeline is cracked. Fig. 14 shows experiment of pressure at a micom gas-meter in our wired and wireless gas safety management system. The state of higher pressures can be occurred when fire is happened in house and gaseous pipelines are heated gradually. The state of lower pressures can be taken place when gaseous is leaked a little and gaseous pipelines or hoses are some cracked.

IV. CONLUSION

We developed and demonstrated through performance test of our gas safety management system using wired and wireless ZigBee ubiquitous sensor network to

improve efficiency of gas safety management. It is important to introduce wireless ZigBee skills into gas safety management technology to make infrastructure of ubiquitous-IT on gas facilities. In recent, people are gradually using many gases and gas safety appliances such as micom-gas-meters, automatic fire-extinguishers, smoke detectors and CO sensors. Therefore effective gas and fire safety management is motivated in buildings. We proposed an effective gas safety management system by using wireless ZigBee sensor network with JN5139. That proposed system will protect an incident in advance and minimize risk ranges. Our system, also, can be applied to ubiquitous city infrastructure for gas safety management facilities. Hopefully, gas incidents will be gradually minimized and then disappeared to these efforts and costs.

Abstract - This work is focused on last mile system called FSO (Free Space Optics). Availability and reliability are estimated from measured fog parameters. In FSO system, the propagation media is air. The FSO systems working in free environment are very popular and establishing of connection is very easy. But on the other hand a number of phenomena in the atmosphere such as scattering, absorption and turbulence cause a large variation of receiving optical power. The influence of absorption and turbulence can be significantly reduced by an appropriate design of FSO link. The visibility has the main influence on quality of the transmission channel. Thus, in typical continental area where rain, snow and fog occur is important to know their values. This article gives us a detail description of the instrument for measuring weather conditions such as the density of fog, humidity and temperature. From the measured data is possible to calculate a visibility which is the main factor for estimation the availability and reliability of FSO link.

I. INTRODUCTION

The free space optics (FSO) communication is a growing up technology, which offers full duplex and usually protocol independent data transmission between two points [6,9]. Distance between transmitting and receiving points can be from several meters up to a few kilometers. It is line of sight technology. Data rates are from hundred of megabits up to a few gigabits. FSO systems have many advantages for example its installation is very easy and fast, there are no expensive fibre optic cables, no expensive rooftop installations required and no spectrum license is required too. FSO systems can currently transmit a large amount of data without mutual interferences with other FSO or RF systems. It is difficult to eavesdropping on transmitted data.

A disadvantage of FSO system is a large variation of receiving signal due to atmospheric phenomena [6]. This fact limits the availability of FSO for a given transmission range, so it is very important to measure and know weather conditions such as fog parameters, humidity and temperature. FSO beams are absorbed and scattered by the air molecules as well as by the solid and liquid particles diffused in atmosphere. Absorption of the signal causes a decrease in signal strength. Scattering does not cause a decrease in signal strength, but it sends off the signal in different directions [1,9].

In following chapter we can find a description of fog sensor, its outdoor and indoor unit. It is a low cost device for measuring weather parameters. In third chapter, there is a way how to calculate values of visibility from measured liquid water content. In final chapter, there are two experiments and their results. We choose one foggy day to illustrate what visibility has influence to availability of FSO systems and one day without dense fog.

II. FOG SENSOR DEVICE

At the campus of Technical University in Košice there is situated a device which is called Fog sensor and which measures data every second, 24 hours per a day about density of fog, temperature and relative humidity [6]. These three parameters are important for subsequent static and statistical evaluation of the quality of FSO communication environment. Fog has the main influence of FSO transmitting quality, which composes of water vapor or water droplets with 100 nm in diameter. In order to estimate the attenuation due to fog, content of liquid water is measured in unit (g/m^3). This task usually requires relatively complex and expensive measuring instruments. In Fig.1 there is illustrated block scheme of experimental Fog sensor measurer, which measures temperature, humidity and fog density in the Laboratory of Optoelectronic systems KEMT FEI TUKE.

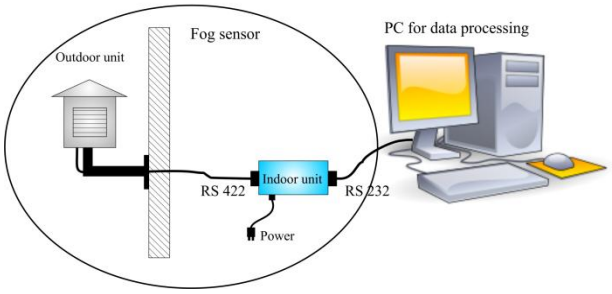

Figure 1. Block scheme of Fog sensor

Fog sensor consists of an Outdoor unit, which performs the measurement. The measured data are sampled in the outdoor unit every 10 ms, then arithmetically averaged by value "Averaging#" and sent to the indoor unit every second. The range of values for value "Averaging#" is from 1 to 1000. In the case referred to TABLE I., the value of "Averaging#" is set at 100.

The Outdoor unit is connected to the Indoor unit with RS-422 line. The Indoor unit is connected to PC through RS-232 line. The measured data are processed in a PC in

several different ways [6]. They can be saved to a file, rendered to chart or stored on server.

The principle of the fog measurement is given in Fig. 2. Outdoor unit regularly sends and receives short infrared optical pulses. Amplitude of the reflected optical pulses is influenced by the reflectance of the elements in the environment. This information is used for a good estimate of liquid water content in the environment. In addition the optical sensor is also equipped with temperature and relative humidity sensors. The sensor is built for the rainy conditions and is shielded from direct sunlight, but allows free movement of fog droplets into and out of the sensor [5].

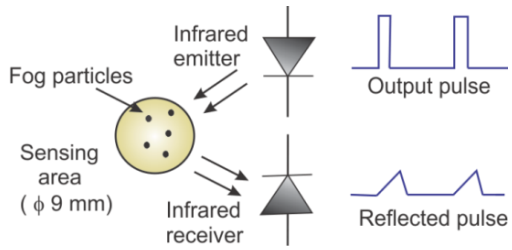

Figure 2. Principle of measurement method

From measured data we can create graph of fog density, temperature and relative humidity (Fig. 3).

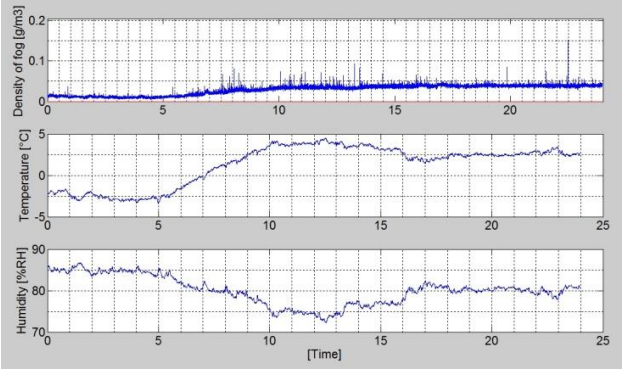

Figure 3. Graphical output of measurement data from the Fog sensor processed in Matlab

All of these values are pre-processed in Matlab that allows us to obtain other parameters which describes availability and reliability of FSO link. This parameter is marked like LWC and it means liquid water content of the atmosphere.

LWC is one of the most important parameters of the fog, which describes the mass of water drops in the volume units of the fog. It is measured in [g/m^3]. Direct method for measuring LWC consist of extracting a known volume trough a cotton pad or of rotating cups in an impeller apparatus, both to the weighed. Also resistance changes can be measured with a hot wire probe attached to an aircraft flying through the clouds. The value of LWC in the fog varies in a wide range. From LWC values fog attenuation can be calculated [10].

III. FOG SENSOR DATA PROCESSING

From fog sensor measured data we can calculate parameter LWC too, but we have to pre-process the measured data from the first column of source data in Matlab (TABLE I.).

TABLE I. SOURCE DATA FROM FOG SENSOR BEFORE PROCESSING

Density (D_i)	Temperature	Humidity	Averaging	Relative Time
227	4006	3121	100	0
213	4007	3121	100	1
213	4007	3121	100	2
218	4006	3122	100	3
211	4008	3121	100	4
216	4008	3121	100	5
216	4010	3121	100	6
216	4009	3121	100	7
258	4010	3121	100	8
215	4008	3121	100	9
218	4009	3121	100	10
214	4009	3121	100	11
214	4010	3121	100	12
215	4009	3121	100	13

For calculation values of fog density we use a source data from first column. Next equation is from manual for software part of fog sensor. (1).

$$F = (D_i . \frac{5}{1024} - 0{,}87) . \frac{0{,}5}{2{,}9} \qquad (1)$$

where F is a density of fog and D_i is fog sensor output value. If we want to get exact value of liquid water content, we need to define a constant which helps us to convert value of fog to value of LWC. This constant is marked as C and it is from ratio between the average liquid water content values W_i and the fog sensor output values D_i.

$$C = \frac{\sum_{i=1}^{n} W_i}{\sum_{i=1}^{n} D_i} = 0{,}7384 \quad [g/m^3] \qquad (2)$$

Where n is number of samples during whole fog event. This constant is used to convert the momentary sensor values D_i to momentary LWC values [2]:

$$LWC = F.C \qquad (3)$$

From LWC we can calculate the visibility. For the calculation we use the empirical formula for fog visibility as a function of fog density:

$$V = d.(LWC)^{-0{,}65} \qquad (4)$$

Where V is a visibility in [km] and parameter d takes on specific values for different fog conditions as shown in TABLE II. below [8]:

TABLE II. TYPICAL VALUE OF PARAMETER "*d*" FOR DIFFERENT TYPES OF FOG

Type of fog	*d*
Dense haze	0,013
Continental fog (dry and cold)	0,034
Maritime fog (wet and warm)	0,06
Dense haze and selective fog	0,017
Stable and evolving fog	0,024
Advection fog	0,02381

In this case, we have mentioned a stable and evolving fog. The stable air mass with cloud cover during the day, clear skies at night, light winds and moist air near the surface. These conditions often occur with a stationary, high pressure area [7].

Thus parameter d has value which corresponds with stable and evolving fog. So visibility is given by the equation below:

$$V = 0{,}024(LWC)^{-0{,}65} \qquad (5)$$

IV. EXPERIMENT AND RESULTS

In campus of Technical University in Košice we have installed two FSO links. In Fig. 4, we can see connections between buildings. First connection is between Laboratory of Optoelectronics Systems (LOS) and main building of Technical University in Košice (TUKE).

Second connection is between LOS and Institute of Computer Technology (ICT).

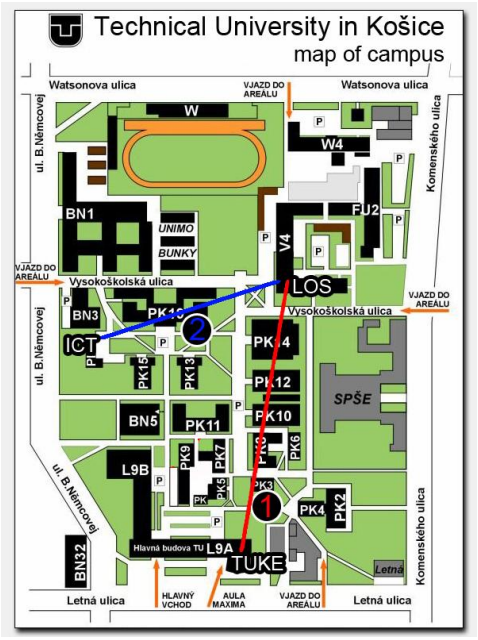

Figure 4. Map of FSO links in campus of Technical University in Košice

For these connections two types of FSO links are used. For both FSO links are used a systems from USA company. First system is from FSONA model SONAbeam 155E (red line). Second link used is from Lightpointe model Flightstrata 155-E (blue line). In next table, there are parameters of these systems (TABLE III.).

TABLE III. PARAMETERS OF FSO LINKS

Parameters	FSONA SONAbeam 155E	Lightpointe Flightstrata 155E
Wavelength	1550 nm	850 nm
Tx Power	100 mW	160 mW
Rx Power	-30 dBm	-30 dBm
Rx Diameter	10 cm	8 cm
Directivity	2 mrad	2 mrad

From these parameters we can obtain a maximum distance in which the links are available. We use our FSO simulator (Software Package "FSO System Simulator"), which gives us information about maximum distance [3,4].

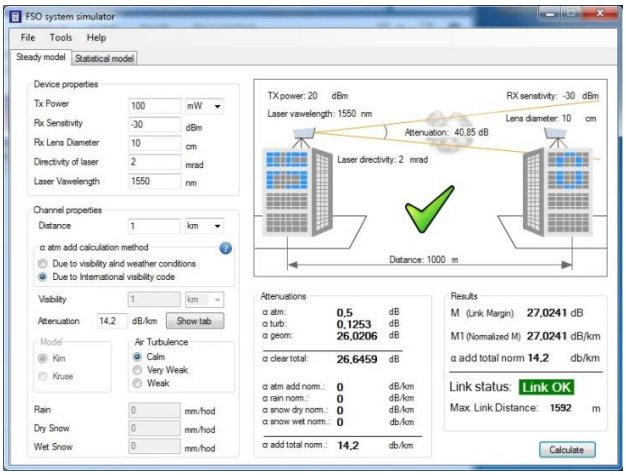

Figure 5. Main window of FSO simulator

In Fig. 5 we can see, that maximum distance for FSONA system is 1592 m. For Lightpointe system this distance is 1190 m. But these distances are in ideal conditions without any unfavorable weather effects and they are our thresholds for next calculation.

In our case we know a distances of both FSO links. First link has 451 m (FSONA system) and second link has 312 m (Lightpointe system) (Fig. 4). From these distances we can say that they are available also at minimum visibilities too. But at all values of visibility lower than the threshold distance, FSO systems will have results in loss of line.

From source data of fog sensor we can calculate an actual visibility in every second per day. In Matlab we can specify the threshold values of distances for both FSO systems. Graph of visibility is created with both thresholds (Fig. 6). For each system, program has created text file with distances which are lower than threshold.

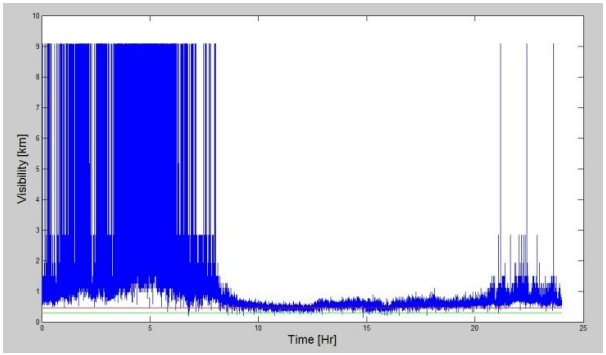

Figure 6. Graph of visibility on 31th October 2011

In this figure red threshold belongs to FSONA system and green threshold belongs to Lightpointe system. From first look we can see that better availability has Lightpointe system. It is true of course, but we know exactly how many percent per a day was link down. In this case from text files we know, that first link was 3004 times per a day down. It is 3,471% of day. Second link was down only 90 times per a day. It is 0,104 % of day. Measurement was performed in a foggy day 31th October 2011. We can calculate that availability of first FSO link was 96,539 % and 99,896 % for second FSO link.

Another day is illustrated in Fig. 7. This data was measured on 15th November 2011. Graph of visibility is illustrated in Fig. 8.

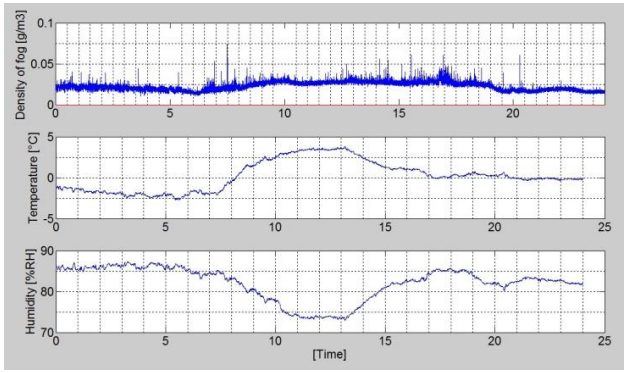

Figure 7. Graphical output of 15th November 2011

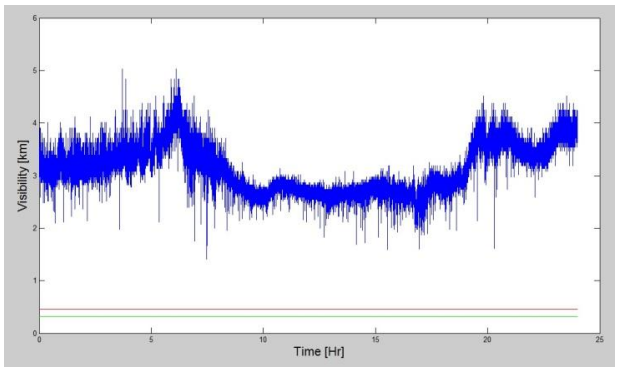

Figure 8. Graph of visibility on 15th November 2011

From these graphs we can see that all values of visibility are higher than thresholds for our systems. So availability of both systems was 100 %.

V. CONLUSION

This paper gives us analysis of fog measurements, which have influence on Free Space Optics laser beams. There are described a relation between liquid water content and visibility. Our Fog sensor gives us these informations. For example density of fog and visibility are different at the Kosice and in our campus in Kosice too. From measure data we can statistically evaluate the availability of FSO links for certain period.

ACKNOWLEDGMENT

We support research activities in Slovakia / Project is co-financed from EU funds. This paper was developed within the Project "Centrum excelentnosti integrovaného výskumu a využitia progresívnych materiálov a technológií v oblasti automobilovej elektroniky", ITMS 26220120055 (50%).

Abstract - This paper will show basics and importance of ergospirometry. Parameters that affect the patient while running and walking will be shown together with principle for determining the Work Load during the test.

The essence of the study and research was to analyze various formulas implemented for determining the power [W] on the basis of patient treadmill training during the ergospirometry performance test.

Four types of calculation in methods of obtaining power (WorkLoad) measurement that are used in the majority of device manufacturers for ergospirometry were analyzed for the load during the ergospirometry test. It is shown that Jaeger formulas compared to ATS, Bruce and Modified ATS Formula, have the best results for different conditions of the experiment, and that they fit in the most testing conditions.

This research has great importance for doctors that interpretate result of test, since using the best possible formula for determining Work Load is of critical importance and it can have influence on determining need for further tests that sometimes include invasive surgery.

Paper also displays shortcomings of mentioned formulas and can be used as a reference when determining which formula is to be used for parameter calculation in a variety of situations.

I. INTRODUCTION

Cardiopulmonary exercise testing is an objective method of evaluating both cardiac and pulmonary function [2]. Cardiac function is evaluated in terms of aerobic capacity and respiratory function is evaluated by dynamic flow volume loops and ventilation – perfusion (VQ) measurements actually performed during exercise [3].

The subject is exercised preferably on a bicycle ergometer or a treadmill [4], [5]. During exercise patient breathes through a mouthpiece which is in fact a minaturised pressure differential pneumotachygraph. The inspired and expired gas is continuously sampled and both oxygen uptake and carbon dioxide elimination is computed. Not only is maximal aerobic capacity calculated but also the point during exercise where anaerobic metabolism is used to supplement aerobic metabolism as a source of energy. That point is very accurately measured via gas exchange data and is termed the anerobic threshold (AT). Cardiac failure may be very accurately assessed in quantified fashion by use of the AT [14].

Ergospirometry is a diagnostic procedure to continuously measure respiration and gas metabolism during ergometer exercise. It enables assessment of function and capacity performance of the cardiopulmonary system and metabolism.

Ergospirometry is made up of the 2 components spirometry and ergometry. The first attempts to measure human gas metabolism while performing quantified physical work can be traced back to the year 1790. The development of procedures to measure gas metabolism and respiration [15] as well as the construction of ergometers in the nineteenth and twentieth centuries are described. Ergospirometry and routinely performed clinical performance diagnosis were introduced in 1929, but it wasn't until the 1950s when the first ergospirometry apparatus which met all scientific requirements was developed.

The parameters used and the physiological and pathophysiological findings by ergospirometry are given in an historical frame. Numerous medical fields have profited from the technique of ergospirometry, for example: cardiology, pneumology, sports medicine, exercise physiology, biochemistry, clinical pharmacology, surgery, orthopaedics, paediatrics and gerontology, besides such global disciplines as preventive medicine, exercise therapy and rehabilitative medicine [8].

II. CONDITIONS FOR CONVERSION TREADMILL EXERCISE TO LOAD

Under specific prerequisites it is possible to convert treadmill exercise to power [12], [13]. This conversion, can't simply be applied to a test subject who is walking or running on a treadmill. In the following will be given some reasons for that and some suggestions for accurate calculation:

1. Depending on the economy of the work of running, the load on two test subjects may be very different, even if they have the same weight, run at the same speed and the same gradient is set.
2. The load highly depends on the used treadmill. A hard treadmill surface requires more energy from the running test subject than an elastic surface, which is showed as example on the Figure 1.
3. Load is even influenced by the shoes the test subject wears. Elastic soles require less energy than hard soles.
4. Because of the difference in motion between walking and running, the load is different, even at the same speed and gradient.

Due to the above mentioned and many other factors, the formulas that will be described in the following text can only result in approximate or standard values [15].

Figure 1 shows example for different lactate production due to different surfaces on different treadmill with the same test subjects and gradient 1,5%.

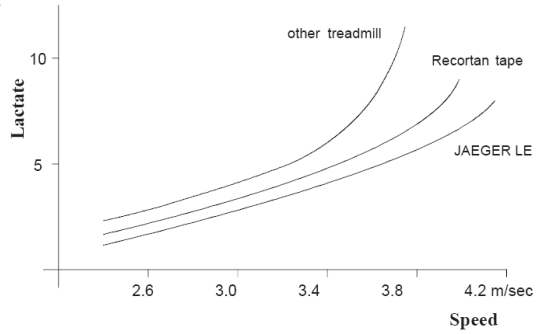

Figure 1. Lactate productions due to different surfaces

III. IMPLEMENTED FORMULAS

In the following text will be presented all implemented formulas in devices for ergospirometry [1] and their disadvantages in practice.

A. ATS Formula

For better presentation of following formulas Figure 2 graphically shows typical situation for this case.

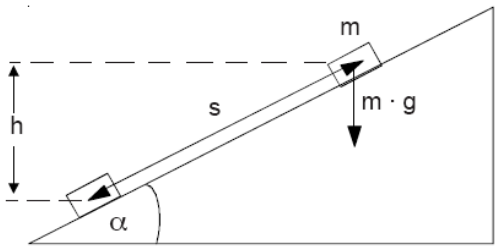

Figure 2. Example for calculation of formulas

From the Figure 2 we can get:

$$power = \frac{work}{time}$$

$$work = m \cdot g \cdot h, \quad where\ is \quad g = 9{,}81 \frac{m}{s^2}$$

$$h = s \cdot \sin\alpha \tag{1}$$

$$s = v \cdot t$$

$$v[m/s] = v[km/h] \cdot \frac{10}{36}$$

Consequently from (1) now we have:

$$power = m \cdot g \cdot v \cdot \frac{t}{t} \cdot \sin\alpha \tag{2}$$

Now we can write it also as:

$$power = BW \cdot 9{,}81 \cdot v \cdot \sin\alpha \tag{3}$$

where is:

BW – Body Weight presented in [kg] and *v* presented in [m/s].

If we convert *v* in [km/h] than we will get:

$$power = BW \cdot 2{,}725 \cdot v \cdot \sin\alpha \tag{4}$$

The same formula can be derived with „grade“ by trigonometry.

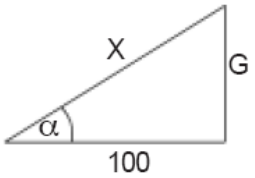

Figure 3. Example for calculation of following formulas

$$\sin\alpha = \frac{G}{X} \quad and \quad X^2 = 100^2 + G^2$$

$$\sin\alpha = \frac{G}{\sqrt{\left(100^2 + G^2\right)}} \tag{5}$$

Now if we use (4) and (5) we will get:

$$power = BW \cdot 2{,}725 \cdot v \cdot \frac{G}{\sqrt{\left(100^2 + G^2\right)}} \tag{6}$$

If we from velocity presented in [km/h] from (6) transform in velocity presented in [mph], than we will get final equation called ATS forumula:

$$power = BW \cdot 4{,}385 \cdot v \cdot \frac{G}{\sqrt{\left(100^2 + G^2\right)}} \tag{7}$$

Besides the above mentioned difficulties in calculating the required values, this formula shows several weak points:

1. Independent of the treadmill speed, a gradient of 0% always results in a load of zero power. This is certainly wrong.
2. The formula does not consider the difference in motion between walking and running.

B. Bruce Formula

The Bruce formula is based on the same consideration as the ATS formula:

$$power = BW \cdot \frac{g}{3{,}6} \cdot v \cdot \sin\alpha \tag{8}$$

For smaller angles of inclination, the following is approximately valid:

$$\tan\alpha \cong \sin\alpha$$
$$g \cong 10\frac{m}{s^2} \qquad (9)$$
$$G = 100 \cdot \tan\alpha$$

The following calculation results in „Bruce“ formula:

$$power = BW \cdot 10 \cdot \frac{v}{3{,}6} \cdot \tan\alpha \qquad or$$
$$power = BW \cdot v \cdot \frac{G}{36} \qquad (10)$$

The Bruce formula and the ATS formula show similar weak points:

1. Independent of the treadmill speed, a gradient of 0% always results in a load of zero power. This is certainly wrong.
2. The formula does not consider the difference in motion between walking and running.
3. Due to the "approximate calculation" ($\tan\alpha \cong \sin\alpha$) the formula can only be used up to a gradient of about 20%.

C. Modified ATS Formula

ATS as well as Bruce assume purely physical conditions, i.e. a horizontal movement without friction requires no work. This can't be applied to a test subject. Thus, the modified ATS formula is to be considered as an attempt to split up the test subject's movement in two parts:

1. The horizontal movement also requires energy. The higher the test subject's weight and the faster he/she moves, the more energy is required:

$$power_horizontal = BW \cdot g \cdot v \cdot K \qquad (11)$$

This energy is required in addition to the upward movement.

2. The energy required for this upward movement can be described analog to the ATS formula:

$$power_upward = BW \cdot g \cdot v \cdot \sin\alpha \qquad (12)$$

Consequently, the total performance can be calculated as follows:

$$power_total = BW \cdot g \cdot v \cdot K + BW \cdot g \cdot v \cdot \sin\alpha$$

or

$$power = BW \cdot 2{,}725 \cdot v \cdot (K + \sin\alpha) \qquad (13)$$

where is $K \cong 0{,}05$ for walking and $K \cong 0{,}06$ for running.

The indicated K values are determined from a data comparison between VO_2/kg/min at different speed and gradient.

D. Jaeger Formulas

Jaeger formulas are based on measurements of the VO_2/kg/min performed on a Jaeger treadmill with different test subjects, determined at different speed and gradient [6].

With data acquired that way, two regression calculations can be made: one for walking and one for running.

a) Walking

$$VO_2[ml/kg \cdot \min] = 5{,}2 + v \cdot (2{,}05 + G \cdot 0{,}29)$$

b) Running

$$VO_2[ml/kg \cdot \min] = 8{,}0 + v \cdot (2{,}11 + G \cdot 0{,}25) \qquad (14)$$

According to Wasserman and Whipp [7] (modified by 10.5 instead of 10.1 or 10.3), oxygen uptake and load correlate as follows (15):

$$VO_2[ml/\min] = 5{,}8 \cdot BW + 151 + 10{,}5 \cdot power$$

Considering (14) and (15) results in the following:

a) Walking

$$W[W] = \frac{[v \cdot BW \cdot (2{,}05 + G \cdot 0{,}29) + 0{,}6 \cdot BW - 151]}{10{,}5}$$

b) Running

$$W[W] = \frac{[v \cdot BW \cdot (2{,}11 + G \cdot 0{,}25) + 2{,}2 \cdot BW - 151]}{10{,}5}$$

where is:

BW – Body Weight [kg];

v – velocity [km/h];

G – gradient [%].

IV. COMPARISON OF DIFFERENT FORMULAS

Comparison between Jaeger, Bruce and ATS formula's was made on statistical comparison of oxygen uptake during exercise on a treadmill [10], [11]. Test subject had 50 kg and runned on Jaeger treadmill on speed of 12 km/h with gradient 3 to 18 % [9].

In this paper comparison between formulas was made also for all other developed formulas on system for ergospirometry.

The first comparison was made on calculated work load at 10 km/h dependent on the gradient with the test subject of 75 kg. The results are shown on the Figure 4 and compared with other three methods used only for experimentaly tests (Gehen, Laufen and Brompton).

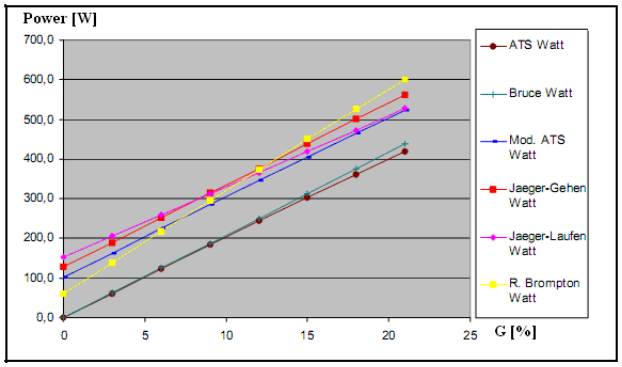

Figure 4. Comparison dependent on the gradient between formulas

Second comparison was made on calculated work load at a gradient of 10 % dependent on the speed with the test subject of 75 kg. The results are shown on the Figure 5 and compared with other three methods used only for experimentaly tests (Gehen, Laufen and Brompton).

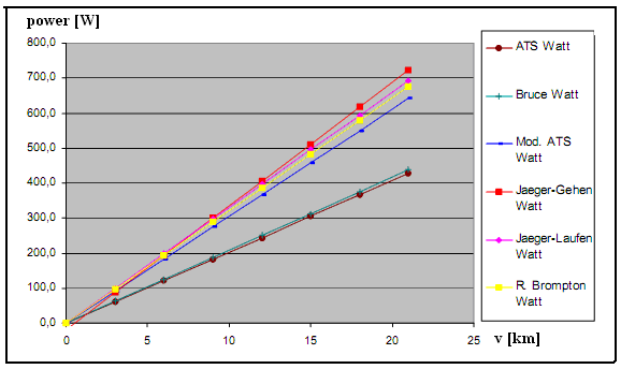

Figure 5. Comparison dependent on the speed between formulas

Based on performed patient tests on actual devices, and obtained results shown on the figures 4 and 5 we can conclude that best tracking of given settings and best results are those from formula used by Jaeger author and modified ATS.

But when we take in to acount cases seen in practice and conditions of work, we can not discard other models, although they make significant deviations on standard tests.

V. CONCLUSION

Based on everything shown in previous four chapters we can clearly see importance of ergospirometry as medical test. Main test parameters influencing Work Load as well as the calculation procedure for each of them.

Chapter two shows problems that can be seen in practice and that are not taken in consideration in result interpretation. Thus, this chapter represents definition of topic of this paper.

Chapter three in detail displays derived and basic relations made by best known authors for performing ergospirometry test. Since this is very important test for the respiratory system as well as cardiovascular system, it is of greatest importance to show shortcomings that occur in everyday testing. This paper shows shortcomings from two sides: engineering side displayed by mathematical correlations, and medical side shown by descriptions of impact of mathematical correlations. Both sides have room for changes and consideration of improving measurements by introducing different formulas and considering different medical interpretation of results and possibly introduction of other variables such as existing medical conditions.

Chapter four simplifies in graphic advantages and disadvantages for each of these formulas performed at same test subject. It is clearly shown that if wrong author is chosen for testing, test results will be inaccurate.

For future work on this topic there is possibility of MatLab modeling of ergospirometry system, where formulas by all authors could be implemented in Simulink environment that will in turn enable corrections of test results using simulations for each formula. Room for improvements is obvious and possible improvements can greatly increase benefits for patients.

Estimation of Muscle Fatigue During Dynamic Contractions Based on Surface Electromyography and Accelerometry

Mislav Jordanic and Ratko Magjarevic
University of Zagreb, Faculty of Electrical Engineering and Computing
Department of Electronic Systems and Information Processing
Unska 3, Zagreb, HR10000, Croatia
E-mails: mislav.jordanic@fer.hr, ratko.magjarevic@fer.hr

Abstract—Common non-invasive measurements of muscle fatigue during dynamic contractions are based on the surface electromyography (SEMG). However, these measurements include movement artefacts such as the change of muscle length and the movement of electrodes. These artefacts significantly contribute to the non-stationary properties of the measured SEMG signal. Consequently, the measurements of the muscle fatigue employ various sensors and signal-processing methods. In this paper, we present a method for the estimation of the fatigue which uses an accelerometer to determine the SEMG segments within which the movement artefacts are resolved and the wide-sense stationarity holds. The fatigue is then estimated by the median frequencies of their power spectra. To illustrate the features of the proposed method, we apply it to the biceps curl exercise.

I. INTRODUCTION

Common non-invasive methods for the measurement of muscle fatigue during dynamic contractions are based on the surface electromyography (SEMG). Such methods are usually based on the detection of the changes in the power spectrum of the SEMG signal to indicate the fatigue of muscle [1]. Namely, the velocity of conduction of muscle fibres decreases with the fatigue. Consequently, the power spectrum of SEMG signal skews and shifts to lower frequencies. Such changes are usually detected using the mean frequency (MNF) or the median frequency (MDF) of the power spectrum [2], [3]. In [4] and [5], it is shown that the MDF approach better detects the fatigue than does the MNF approach.

In literature, for example in [1] and [6], the authors consider the SEMG signal as a non-stationary stochastic process whose probability density function is the Gaussian function. However, such a model of the SEMG signal makes the calculation of the MDF a nontrivial task. On the other hand, during the measurement of the SEMG signal, several problems arise. Namely, the dynamic contraction of muscle causes the movement of electrodes respect to the muscle fibres and the change of length of muscle fibres. Such problems are still challenges in the processing of SEMG signals [7]–[10]. Recently, various methods which overcome these problems have been proposed, such as the methods based on the short-time Fourier transform [8], the wavelet transform [9], and the Hilbert-Huang transform [10].

In this paper, we present a method for the estimation of muscle fatigue based on the median frequency of the SEMG signal. To obtain the MDF, we employ the Fourier transform on the segments of the SEMG signal within which the movement artefacts are resolved and the wide-sense stationarity holds. To find the relevant SEMG segments, we employ the detection of movement which uses the acceleration measured during the dynamic contractions. This detection has already been developed in [11]. Therefore, we use the method in [11] in the first stage of the fatigue estimation.

II. MESUREMENT SYSTEM

We perform the fatigue estimation of the *biceps brachii* muscle during a biceps curl exercise. The exercise is illustrated in Figure 1.

The measurements are obtained by using the instrumentation described in [12]. It contains a digital triaxial accelerometer and an amplifier for SEMG signal. It is located on the subject's wrist and records the SEMG signal sampled with 1000 Hz and the accelerometer signal sampled with 100 Hz on a microSD memory card. After the exercise, the data are transferred to a computer, where the fatigue estimation is performed off-line in MATLAB environment.

For recording of SEMG signal, bipolar electrodes (Ambu Blue Sensor, type SE-00-S) are placed on the *biceps brachii*, following the Seniam project recommendations [13]. The measurement system is shown in Figure 2.

III. MUSCLE FATIGUE ESTIMATOR

Our objective is to estimate the muscle fatigue by using the median frequency of the power spectrum of SEMG signal. The advantage of such an approach is that the power spectrum of the SEMG is estimated on a short time-domain segment extracted during each exercise repetition. Namely, during these segments, muscle length

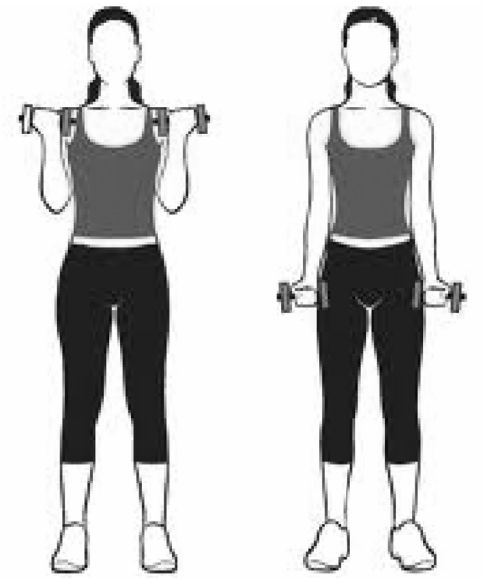

Figure 1. Illustration of biceps curl exercise.

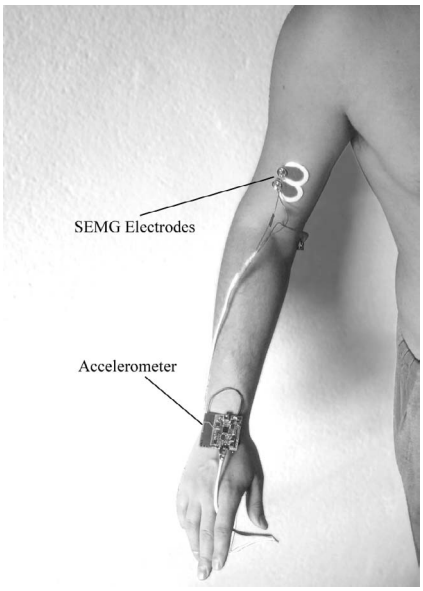

Figure 2. Illustration of measurement system.

and position of electrodes respect to active muscle fibres are constant throughout the exercise. This procedure greatly reduces the influence of non-stationary effects caused by dynamic contractions. The segments for the estimation of the power spectrum are obtained by employing a movement detector and an accelerometer placed on the subject's wrist.

A. Movement Detector

A biceps curl is a sagittal-plane movement. Therefore, only the accelerometer axis parallel to the forearm is used for the detection of movement. The recorded signal is mostly composed of the gravitational acceleration, and takes values from −1g, during the extension phase of the exercise, to 0.8g, when the arm is fully flexed. This is illustrated in Figure 3.

The detector of movement is designed by using the method described in [11]. In the paper referred to, the authors propose the detection of movements from the acceleration which is processed by the filter with symmetric impulse response [14]. This filter introduces the minimum time-domain distortion and ensures high selectivity. Therefore, the waveform corresponding to the movement can be efficiently extracted from the acceleration.

In [11], the acceleration signal is filtered by using the fifth-order SIR filter with the symmetry of the impulse response about the line t=1s. The local maxima of the filtered signal correspond to the detected movements. The maxima occur at the points denoted as t_C, what is illustrated in Figure 3. Furthermore, the points corresponding to the maximum changes of the filtered signal are used to estimate the duration of the movement, T_M. The estimation is performed separately for the rising and the falling part of the filtered signal. The duration of the rising part is estimated as the double value of the period between the maximum positive change and the

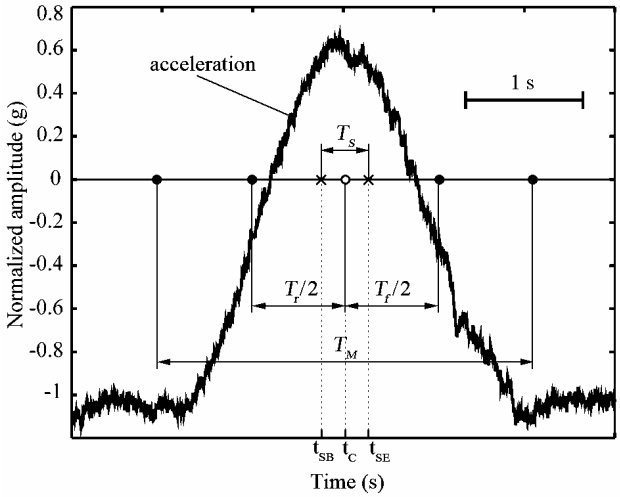

Figure 3. Principle of movement detection and finding the interval for power-spectrum estimation based on acceleration.

corresponding local maximum. Similarly, the duration of the falling part is obtained as the double value of the period between the local maximum and the maximum negative change. The duration of a movement is calculated as

$$T_M = T_r + T_f \tag{1}$$

where T_r is the duration of the rising part, and T_f is the duration of the falling part.

We propose the estimation of the power spectrum on a short SEMG segment, with duration T_S, corresponding to one movement. The duration of the segment is defined as

$$T_S = t_{SE} - t_{SB} \tag{2}$$

where t_{SB} and t_{SE} are the beginning and the ending point of the segment. They are estimated by

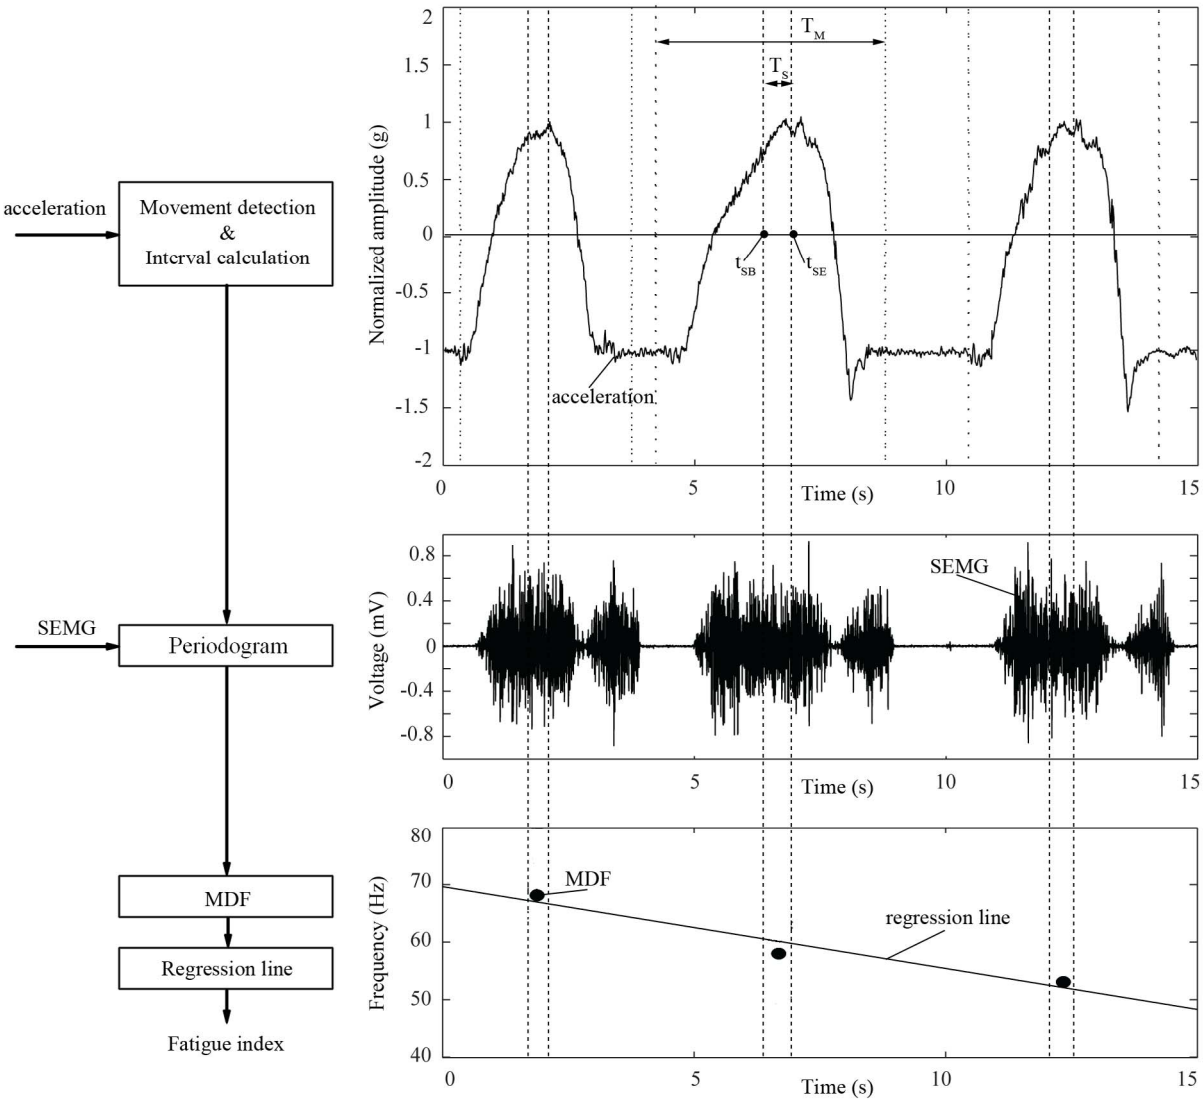

Figure 4. Block scheme of muscle fatigue estimator. Vertical dashes represent time-domain segments within which SEMG periodograms are calculated.

$$t_{SB} = t_C - \frac{T_M}{16} \tag{3}$$

$$t_{SE} = t_C + \frac{T_M}{16} \tag{4}$$

It should be noted that the SEMG power spectrum is estimated over one-eight of a contraction period, within which the forearm is fully flexed and the velocity of the movement reaches the minimum. In practice, such an estimation of the period results in low non-stationary effects.

B. Fatigue Estimation

The block scheme of the proposed muscle fatigue estimator is shown in Figure 4. In the estimator, the power spectra are obtained by using the modified periodograms over SEMG segments determined by the movement detector. Each periodogram is calculated by using the discrete Fourier transform (DFT) in L points, as in

$$S[k] = \frac{1}{LU}\left|\sum_{n=0}^{L-1} s[n]\cdot w[n]\cdot e^{-j2\pi kn/L}\right|^2,\ k = 0,1,...L-1 \tag{5}$$

where $s[n]$ is sampled SEMG signal within the period of T_S, and $w[n]$ is the window. In the estimator, we use the Hamming window which has the same length as the DFT. Constant U ensures unbiased spectrum estimation and it is defined as

$$U = \frac{1}{L}\sum_{n=0}^{L-1} w^2[n] \tag{6}$$

To obtain the median frequency of the periodogram $S[k]$, first we have to find the corresponding index, m. The index of median frequency is obtained by solving the equation

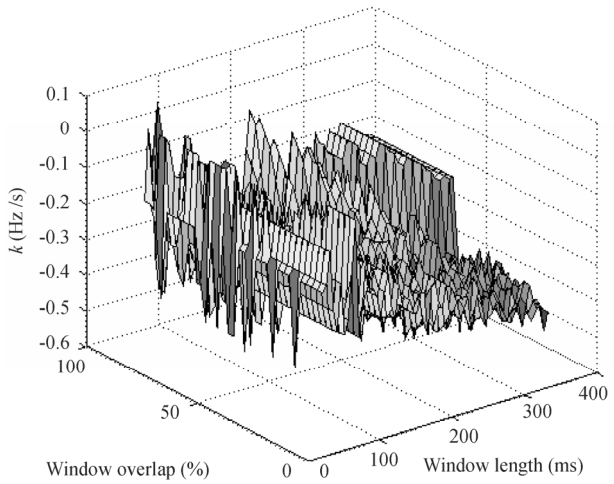

Figure 5. Influence of Welch parameters on fatigue index, *k*.

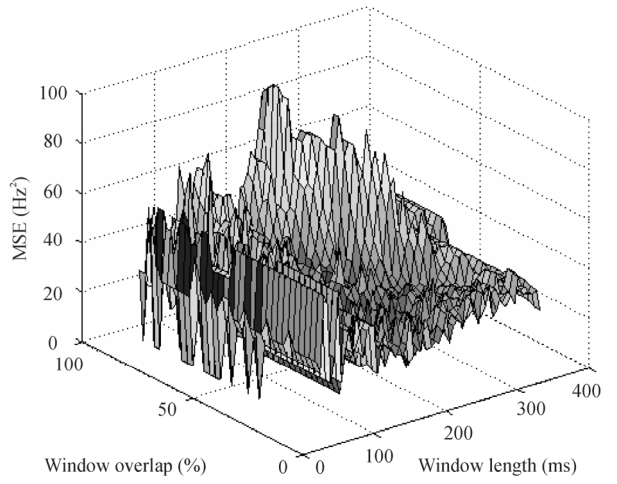

Figure 6. Influence of Welch parameters on mean squared error.

$$\sum_{k=0}^{m} S[k] = \sum_{k=m}^{\lceil L/2 \rceil} S[k] \tag{7}$$

where $\lceil . \rceil$ denotes the next higher integer value. It is clear that the periodogram in (5) corresponds to the frequency range [0, 2π). However, for the calculation of median frequency, only positive frequencies are sufficient. Therefore, k in (7) runs from k=0 to k=$\lceil L/2 \rceil$ rather than to k=L−1.

After m is found, the median frequency is obtained as

$$MDF = m \cdot \frac{f_s}{L} \tag{8}$$

where f_s is sampling frequency. The value of MDF describes the frequency content of each exercise cycle. As we mentioned earlier in the introduction, during sustained muscle contraction, the power spectrum of the SEMG is shifted towards lower frequencies. Therefore, the regression line of the median frequencies can be used for the monitoring of the fatigue [8], [10].

The regression line is calculated in order to fit the MDF values in the least-square sense. The line is given by

$$y = kt + b \tag{9}$$

where k and b denote the slope and the y-intercept. The slope of the obtained regression line indicates the shift of the power spectra from higher to lower frequencies due to muscle fatigue. Therefore, we chose k as the figure of merit in the estimation of muscle fatigue, called the fatigue index [8], [10].

Let us now compare the values of the fatigue index obtained using the power spectrum based on a single periodogram and the power spectrum obtained by a common method, such as the Welch method [15]. The Welch method involves dividing the signal into overlapping segments, calculating their modified periodograms, and averaging the obtained periodograms. This method reduces the variance of the estimated spectra in exchange for the frequency resolution, what is usually a beneficial tradeoff.

For illustration, we run the Welch method with the following parameters:

- $w[n]$ is the Hamming window
- window length, L, corresponding to the periods from 30ms to T_S with the step of 10ms
- window overlapping from 10% to 90% with the step of 5%

Figure 5 shows the fatigue index as the function of Welch's parameters for the exercise in which the mean of durations of SEMG segments is 410ms. It is clear that the changes in k are low when the window length is close to the durations of SEMG segments, T_S. In addition, similar behavior is also obtained for the mean squared error (MSE) of median frequencies. Figure 6 shows the MSE as the function of Welch's parameters for the same exercise. It should be noticed that the MSE is low when the window length is close to T_S. Following this analysis, reasonably good estimation of the fatigue index can be simply obtained by using the periodograms with the lengths equal to T_S.

IV. Measurement Examples

Three subjects were tested during the biceps curl exercise. The subjects were all 23 years old and had 91kg ± 3kg. They were carefully chosen to have similar anatomy and similar sports history in order to be tested with the same weights.

After a short warm-up, the subjects were instructed to perform 10 repetitions of the biceps curl exercise with the weight of 3kg. Figure 7 shows the SEMG signal and the regression line obtained during the exercise. Since the subjects did not feel the fatigue, the index of fatigue was

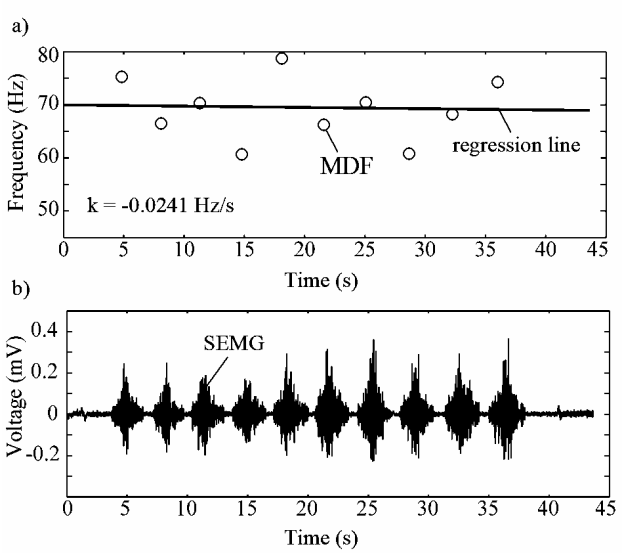

Figure 7. Regression line (a) and SEMG signal (b) during exercise without muscle fatigue.

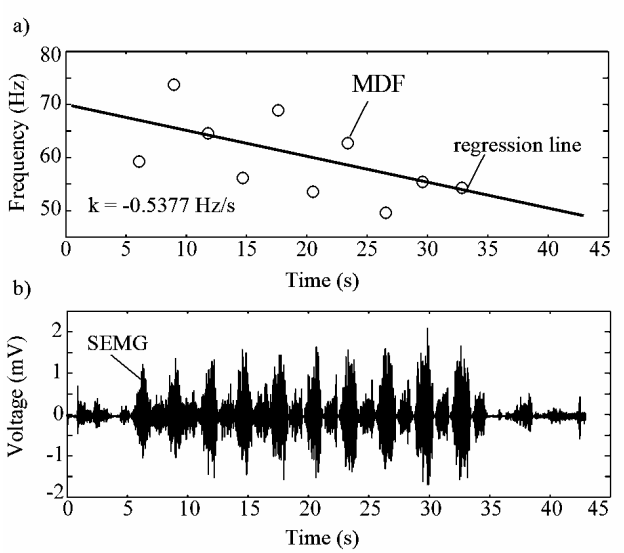

Figure 8. Regression line (a) and SEMG signal (b) during exercise with muscle fatigue.

low. After this exercise, the subjects were instructed to perform the same exercise but with the weight of 12kg. Figure 8 shows the obtained SEMG signal and the regression line. It is clear that a significant change in the index occurs, what alerts the fatigue.

V. CONLUSION

A method for the estimation of local muscle fatigue during dynamic contractions was presented. The method employed the electromyography and the accelerometry technique to indicate the fatigue. The fatigue was quantified by the fatigue index. It was defined as the slope of the linear regression model fitting the median frequencies of the electromyographic signal in the least-square sense.

The method was implemented in MATLAB environment. Such an implementation requires off-line calculation. However, the off-line monitoring is usually acceptable in many medical applications, such as the physical rehabilitation.

Abstract - Dynamic monitoring of patient body weight distribution in biomechanics laboratory can provide useful information for research and diagnosis purposes. The examinee can be subjected to different conditions, either standing still or doing a set of predefined exercises. Human locomotor system maintains the body balance in a complex manner, thus resulting in very small weight distribution perturbations which can provide a better insight in the patient state and serve as an excellent practical diagnostic tool. This paper describes an implementation of biomechanical scale designed to enable a high resolution dynamic body weight distribution measurement, along with monitoring of the angle and the distance between feet in the real-time.

Keywords: biomechanics, dynamic weight distribution measurement, electronic instrumentation

I. INTRODUCTION

Monitoring the patterns of postural responses in a process of maintaining the equilibrium state of upright stance through the muscle activity perturbations can provide a better insight into a state of human locomotor system. The possibility of dynamic monitoring of small postural changes in a process of achieving the body balance is important in for researchers in many fields, such as biomechanics, medicine, sports, and rehabilitation. Such information can be especially useful for understanding the mechanics of normal and pathological movement of patients with various motor deficiencies [1], [2].

Different measurement methods and approaches were proposed to provide means for capturing these small postural changes of human locomotor system. The most appropriate approach depends on specific objectives of the examination or research. Some of the existing approaches encompass the methods of center of pressure (COP) or center of gravity (COG) monitoring using force plates [3], swaymeter [4], ataxiameter [5], motion capture and analysis techniques using digital cameras [6] etc.

The information acquired for static and dynamic balance conditions are useful to describe, analyze and parameterize biomechanical models of human body. Various signal and information processing techniques are used to extract parameters of such models [7] - [11]. The information processing algorithms and development of new measurement methods are subject of intensive scientific research.

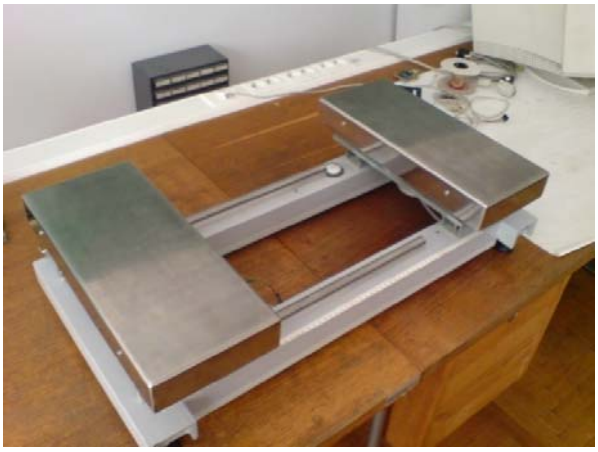

Fig 1: Biomechanical scale for dynamic measurement of human body weight distribution

In this paper we propose an implementation of biomechanical scale, specifically designed to monitor dynamic parameters of human posture perturbations in the process of maintaining the body balance. The instrument was designed to provide means of capturing body weight distribution separately for each leg with high-resolution and accuracy, along with information about the separation distance between feet, and orientation for each foot. These parameters are monitored and recorded in a real-time while the examinee is standing still or doing some set of predefined exercises following the instructions from operator or doctor.

The paper is organized as follows. Section 2 presents an overview of the main system requirements and architecture. Section 3 describes details of measurement system hardware implementation. Section 4 gives an overview of the accompanying visualization and data processing software. Section 5 provides the preliminary results of laboratory test and measurements.

II. MEASUREMENT SYSTEM OVERVIEW

The biomechanical scale for dynamic human body posture analysis was designed taking into account various mechanical, electrical and software requirements. The most important initial measurement system specifications were the following:

- dynamic measurement of the human body weight distribution on each foot (in the frequency range up to 500 Hz),

- real-time measurement of angle and distance between feet during the examination,
- automatic calibration of the multi-channel input measuring chain,
- digital communication with personal computer (PC) through the USB and wireless ISM radio link,
- PC software for real-time measurement information visualization, processing and storage,
- database support for the examinee record management.

The architecture of the system is shown in Fig. 2.

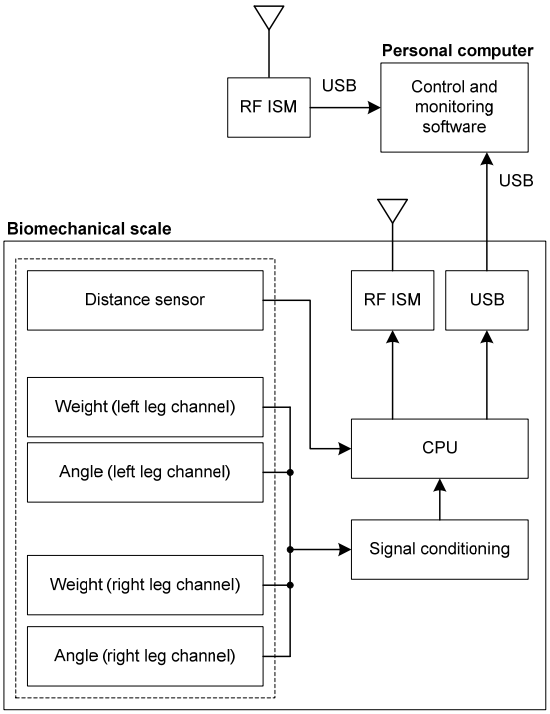

Fig 2: Functional system block diagram

The system can be divided into two major parts: the biomechanical scale hardware (measuring instrument), and the personal computer running the visualization and analysis software. The biomechanical scale consists of the custom-designed mechanical body, sensors for measuring the quantities of interest (body weight distribution, distance and angle between feet), and the embedded microprocessor board with measurement electronics and communication interfaces. Two different communication interfaces are provided: wired USB and wireless ISM (Industrial, Scientific and Measurement) radio-frequency (RF) link. These options enable higher flexibility in practical system deployment scenarios: while the USB provides more robust and faster wired communication interface, the wireless RF ISM option enables that physical dislocation of the personal computer from the scale (e.g. at the other corner of the laboratory). That can ease up the measurement setup installation and reduce the wire clutter which can disturb the experimental conditions. We implemented custom ISM RF link in order to minimize the software and hardware complexity, both on the instrument and PC side (e.g. implementing WiFi or Bluetooth on the instrument side would increase the system implementation complexity). This approach needs only one small additional ISM RF transceiver connected to PC through the USB interface.

The typical experiment in biomechanics laboratory with this measuring system is conducted under the control of PC monitoring software. During the phase of experiment preparation, the operator monitors the waveforms of the body weight distribution fluctuations in a real-time, along with distance and angle between feet. After the subject under examination is ready, the experiment can start. The operator instructs the examinee about the exercises which should be performed and monitors the dynamic behavior of measured waveforms in a real-time. All raw measurements are automatically recorded and stored into patients database for the future reference and off-line analysis.

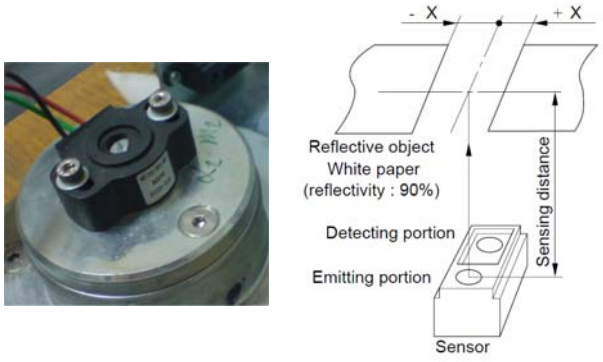
The system calibration for each measuring channel must be conducted periodically, following the procedure built into the software. The reference channel responses are recorded (zero and gain levels) and they are used in subsequent measurements.

III. HARDWARE DESCRIPTION

The mechanical body of the scale (Fig. 1) consists of custom designed mechanical elements, carefully fabricated to accommodate necessary application-specific requirements. The body of the biomechanical scale is built around the metal base frame with two platforms attached, one for each foot. Each platform is moveable with two degrees-of-freedom: platforms can move in a lateral direction (variable distance between feet), and they can rotate around the axis perpendicular to the reference base plane (variable and independent angle for each foot). Mechanical elements were designed to withstand the overall subject weight of 150 kg.

Each platform where the examinee stands on is attached directly to the load-cell sensor. The weight applied on the each platform reflects the body imbalance dynamically monitored by the measurement system. We used two HBM (Hottinger Baldwin Measurements) PW10C3-MR load-cell sensors for weight distribution measurement. Tensometer resistance for this sensor is 350 Ω and the nominal sensor sensitivity is (2,0 ± 0,2) mV/V. The full scale measuring range for each body weight input channel is 150 kg.

Between each platform and load-cell sensor an additional element for measuring the angle was placed. We employed a simple resistive potentiometer sensor (Fig. 3a), which changes the resistance linearly with the measured angle. Distance between feet is measured by means of the optical sensor. The sensor consists of infrared LED emitter and photodetector (Fig. 3b). The distance is measured indirectly by measuring the intensity of reflected IR emission. The mechanical construction of the scale incorporates the optical sensor with emitting and detection portion on one platform and the reflective area on the opposite one. We used the Sharp GP2D02 optical distance sensor with digital output, which can be easily interfaced directly to the microcontroller, without a need for additional signal conditioning circuitry.



(a) (b)

Fig 3: Built-in sensors:(a) angle measurement sensor, (b) optical distance measurement sensor

The biomechanical scale hardware is built around C8051F133 microcontroller, which features a fast modified single-cycle 8051 core, 64 kB flash, 8 kB RAM, I2C, SPI, 2 UART interfaces etc. The CPU controls the process of real-time data acquisition from multiple measuring channels, packet handling and data streaming to PC visualization and monitoring software through USB and ISM radio-frequency interfaces. Samples are acquired from two weight measurement channels, two angle measurement channels, and one distance measurement channel. Measurements from weight and angle input channels are sampled by means of the high-resolution multichannel sigma-delta A/D converter, and they are read out by microcontroller through the SPI interface. Distance measurements are read out by microcontroller directly from the sensor digital output, using the proprietary synchronous serial interface.

The sampling rate for each channel can be controlled by software. Although it is possible to sample each channel with high speed (1 kS/s or more), it would impose relatively high requirements on data link. Taking into account that the samples from two weight and two angle measurement channels are coded in 24-bit resolution (the native resolution of ADC, although the effective number of bits is smaller), this would impose a need for 96 kbps data link, plus overhead of distance measurement samples. While this speed is easy to accommodate for USB, most of out-of-the-box ISM RF modules available on the market work with less effective throughput. Moreover, overly high sampling rate impose additional unnecessary overhead for packet handling in microcontroller and real-time data processing in PC software. We concluded that it is sufficient for most applications to sample weight measurement channels with 200 samples per second, and angle and distance measurement channels with 10 samples per second, what requires only approx. 10 kbps of effective data throughput.

The microcontroller has two built-in UART interface modules which are used to implement two simultaneous separate serial communication channels. First UART module is connected to the FTDI232 RS232/USB bridge integrated circuit, which provides wired USB connectivity by means of the VCP (virtual comm port). Second microcontroller UART port is connected to the XBee Pro transceiver module (XBP24-Z7CIT-004). This module provides transparent wireless UART operation without an additional overhead in the microcontroller embedded software, because it can be employed like plug-in module be simply connecting to microcontroller UART interface. XBee Pro module operates in a license-free 2.4 GHz ISM band, with programmable output power (up to +18 dBm) and high speed RF data rate (256 kbps). It provides means for establishing two-way data link between the instrument and computer for additional control and flexibility.

IV. Measuring Data Visualization and Analysis Software

The control and monitoring PC application was developed using the MS Visual Studio 2008 package and C# programming language, as Windows Forms .NET desktop application. The software implements the following major features:

- main window with menu driven interface for experiment monitoring and control,
- communication layer with protocol for decoding the data stream received from the measuring instrument and for sending control messages to the device,
- USB and RF ISM communication link,
- graphic widgets for real-time visualization of waveforms representing the examinee weight distribution, angle and distance between feet,
- numerical representation of the averaged measurements,
- real-time data processing and storage (averaging, imbalance calculation, filtering etc.),
- user interface for instrument calibration,
- database management of patient information and storage of raw experimental data,
- data export for 3rd party applications (Excel, Matlab etc.).

The application contains a minimum number of external dependencies (.NET Framework 2.0, MS SQL Express Edition for database management). Data visualization was implemented by custom designed .NET controls based on GDI+ API.

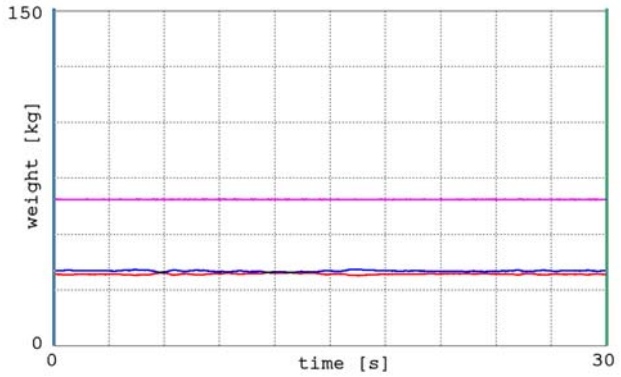
V. Results

The biomechanical scale was implemented and tested in the laboratory. The preliminary test results and technical characteristics are summarized in Tab. 1. The laboratory measurements showed that the prototype was realized according to the specifications noted in Section 2. The most important aspect of the realized measuring system is that it is capable for a high-resolution and fast human weight distribution capture and monitoring, with sampling rates of few hundreds samples per second, and the absolute accuracy better than 50 g. The uncertainty of measuring the angle between feet is around 1°, while the accuracy of measuring the distance is around 1 cm.

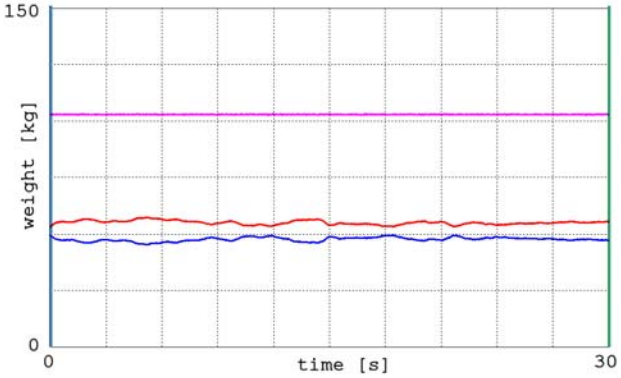
Tab 1: Technical characteristics of the biomechanical scale

Parameter	Value
Weight measurement range	300 kg
Distance measurement range	60 cm
Weight measuring channel uncertainty	50 g
Angle between feet channel uncertainty	1°
Distance between feet channel uncertainty	1 cm
Maximum sampling rate (weight, angle)	1 kS/s
Maximum sampling rate (distance)	10 S/s
Maximum RF transceiver output power	+18 dBm
Maximum RF ISM data rate	115,2 kbps
Communication interfaces	USB, ISM (2,4 GHz)

The measurement system was tested on a small group of examinees. The results of experimental measurements obtained for two representative subjects are shown in Fig. 4 and Fig. 5. Each examinee was instructed to stand still on the scale while the instrument was recording and analyzing the acquired measurements for 30 s. Fig. 4 shows the weight distribution waveforms for two examinees, A and B. The red and blue lines show the dynamic weight distribution for right and left platforms, respectively, while the violet line represents the sum, i.e. the total body weight. One can notice that variations in weight distribution and body imbalance are smaller for subject A.

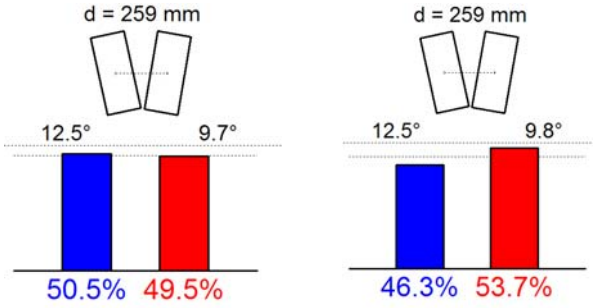


(a)



(b)

Fig 4: Dynamic weight distribution for examinees A (a) and B (b); right and left platform components are shown in red and blue, respectively, while the violet line represents the sum (total body weight)



(a) (b)

Fig 5: Measured distance and angle between platforms for each leg for examinees A (a) and B (b), along with graphical representation of averaged weight distribution for each leg

Fig. 5 shows the distance and angle between platforms for each leg for both examinees, along with the graphical representation of the overall averaged weight distribution imbalance over the whole period of recording. The numerical analysis of measurement results is shown in Tab. 2 and Tab. 3.

Tab 2: Examinee A dynamic weight distribution measurement summary

Parameter		Value
Left leg weight (mL)		
	Mean	33,6 kg
	Standard deviation	0,2 kg
	Minimum	32,8 kg
	Maximum	34,3 kg
Right leg weight (mR)		
	Mean	32,3 kg
	Standard deviation	0,2 kg
	Minimum	31,5 kg
	Maximum	33,1 kg
mL : mR		51,0% : 49,0 %
(mL – mR) / m		2,0 %
m = mL + mR		65,9 kg

Tab 3: Examinee B dynamic weight distribution measurement summary

Parameter		Value
Left leg weight (mL)		
	Mean	47,8 kg
	Standard deviation	0,8 kg
	Minimum	45,5 kg
	Maximum	49,8 kg
Right leg weight (mR)		
	Mean	55,4 kg
	Standard deviation	0,8 kg
	Minimum	53,4 kg
	Maximum	57,9 kg
mL : mR		46,3% : 53,7 %
(mL – mR) / m		-7,4 %
m = mL + mR		103,2 kg

The numerical analysis was conducted for the set of samples collected during the predefined recording period of 30 s. For each leg weight measurement channel the program calculated the mean weight, standard deviation, minimum and maximum measured value. The examinee body imbalance ratio (*mL : mR*) was estimated from the averaged signal for each leg platform. The relative body imbalance $(mL - mR) / m$ was calculated from average weights difference relative to total body weight (*mL* + *mR*). The results of conducted experimental test clearly shows that the subject B exhibits substantial body imbalance in this example.

VI. CONCLUSION

The biomechanical scale for dynamic measurement of human body weight distribution, angle and distance between feet was implemented and tested. The measurement unit consists of custom designed mechanical platforms with built-in sensors (load-cells, potentiometer angle and optical distance sensors), microcontroller-driven measurement unit with signal conditioning hardware, power supply, and the communication interfaces (USB and 2.4 GHz ISM wireless link). The software for personal computer contains GUI for measurement unit control, real-time multichannel data visualization and processing, and patient database management. The implemented prototype was tested in laboratory and showed that the instrument is capable of measuring fast human weight distribution perturbations with high-resolution and accuracy. The proposed measurement system can provide a valuable tool for diagnostic and research purposes in the fields of biomechanics, sport, medicine, and rehabilitation.

Abstract - The need for hearing aids is growing and manufactures are coming up with new technologies (digital and DSP) to make these devices more attractive and effective. Users of those devices who were not always hearing impairments are divided into several groups: audio masters - ton masters, audio engineers, and young people exposed to excessive noise levels, older people, and persons with disabilities. The procedures of getting audiogram were analyzed, as well as the ways of setting (DSP) device characteristics related to individual patients. AB tests are carried out, and based on obtained results, distinctive processes or devices that can enable people with hearing loss well music listening were evaluated (mono, hi- fi stereo, surrounding sound).

I. INTRODUCTION

Musicians experience significant sound exposures, most will develop some degree of music induced hearing loss. Other professionals in the music industry-audio engineers, recording engineers, managers, disc jockeys, etc. - also experience significant exposures, and they are also at risk for hearing loss and cochlear damage.

Recently, the professional journals have published more articles relating to listening to music through hearing aids and cochlear implants. For some people, being able to hear music well may be as important as speech communication. Music as an input poses some problems both for the hearing aid design engineer and for the hearing health-care professional.

The traditional hearing aids were designed with the goal of optimally responding to the acoustic characteristics of a speech signal, not music. The acoustic characteristics of music are quite different from speech, and a hearing aid that is well for speech may not be appropriate when listening to music. There are important consequences emanating from this design requirement.

For example, the range between the softest sound of speech and loudest is about 30 to 35 dB, while the loudest speech signal rarely exceeds 90 dB. The current digital hearing aids are designed to process this range of speech input. In music this is in the order of 100 dB, and the most intense sound as high as 120 dB. With music selections hearing aids with less than 16 bit A/D converter may produce to high levels of harmonic distortion. And hearing aids that do well with music are those with wide frequency ranges and little distortion- high fidelity hearing aids. The aids judged to reproduce music with higher fidelity were also the ones with which hearing aids users under tend speech best.

II. HEARINGIMPAIRMENT

Hearing impairment is defined as a lack or reduction in the ability to hear clearly due to a problem somewhere in the hearing mechanism. A hearing impairment can occur in the outer, middle or inner ear along the pathway to the brain. A complete adiological assessment consisting of many tests will best determine and specify the type of hearing loss a man has.

There are three types: conductive, sensorineural and mixed hearing loss. A conductive hearing loss is a result of damage to outer or middle ear. Conductive hearing losses are not severe and often times can be surgically corrected. A person with conductive hearing loss may reap great benefits from hearing aids. Sensorineural hearing loss is a result of damage to the hair cells of the inner ear or nerves. This type of hearing loss ranges from mild to profound and is permanent.. The surgery cannot be performed to correct a sensorineural hearing loss. Often times, hearing aids are not helpful.

A mixed hearing loss means that the hearing loss problem occurs in the outer or middle and inner ear.

Central hearing impairment occurs when auditory centers of the brain are affected by injury, disease, and tumor, hereditary or unknown causes. Loudness of sound is not necessarily affected, although understanding of speech, also though of as –clarity-of speech may be affected. Central hearing loss has more to do whit the brain than the ear.

The audiologist and the physician work collaboratively to determine if hearing loss is sensorineural or central.

There are distinct degrees of hearing loss. Hearing loss is often classified by distinct categories. Below is a chart that lists and classifies the degrees of hearing loss according the dB range in which sound be heard.

Mild hearing loss: The people can hear with their better ear the most quit sounds between 25 and 40 dB. The people who suffer from mild hearing loss have some problem with conversation, especially in noise surrounding.

Moderate hearing loss: On average, the most quit sounds heard by people with their better ear are between 40 and 70 dB. They have difficulty keeping up with conversation when not using a hearing aid.

Severe hearing loss: On average, the most quite sounds heard by people with their better ear are between 70 and 95 dB. The people who suffer in severe hearing

TABLE I. DEGREES OF HEARING LOSS

Degree of hearing loss	*Range [dB]*
Normal hearing dB	0-25
Mild Hearing Loss	26-40 dB
Moderate Hearing Loss	41-70 dB
Severe Hearing Loss	71-90 dB
Profound Hearing Loss	>91

loss will benefit from powerful hearing aids, but often they rely on lip-reading even when they are using hearing aids.

Profound hearing loss, on average, the most quit sounds heard by people with their better ear are from 95 dB or more. People who suffer from this hearing loss are very hard of hearing and rely mostly on lip-reading, and/or sign language,

A. HEARING TEST

A hearing test comprises a number of different examinations. The one phase of examination was main hearing test which is conducted in a quit soundproof room. The main hearing test includes following tests: the pure ton, test. The speech test and the middle ear test. We are used all of these tests and result is also audiograms, which gives a detailed description of our hearing abilities and which are described as a pictures of our sense of hearing. During hearing tests the results are recorded on the audiograms.

B. HEARINGS AID TYPES AND STYLES

There are many types and styles of hearing aids. The type and degree of hearing loss, power requirements and option, manual dexterity abilities, cost factor, and cosmetic, concern are some of the factor that will determine the exact hearing aid type the patient will use. The most common types are below listed.

BTE ;Behind-the ear hearing aids consist of a hares plastic case worn behind the ear and connected to a plastic ear mold that fits inside the outer ear. The electronics parts are held in the case behind the ear. BTE aids are used by people of an all ages for mild to profound hearing aids.

A new kind is an open-fit hearing aid. Small, open-fit aids fit behind the ear completely, with only a narrow tube inserted into the ear canal, enabling the canal remain open. For the this reason open-fit hearing aids may be a good choice for people who experience a build up of earwax, some people may prefer the open-fit hearing aid because their perception of their voice dos not sound „plugged up“.

ITE: *in–the-ear* devices are probably the most comfortable, the least expensive and easiest to operate. They are also the largest of the custom made types. ITE hearing aids are completely inside the outer ear and are used for mild to severe hearing loss. Some ITE aids may have certain added features installed, such a telecol, that allows users to receive sound through circuitry of the hearing aids, rather than through its microphones. A telecoil also helps people hear to public facilities that have installed special sound systems. Induction loop systems can be found i churches, schools, airport, and auditoriums.

Canal hearing aids fit in the ear canal and are available in two styles:

ITC: *in-the-canal* hearing aids are made to fit the size and shape of a man’s ear canal.

CIC: *completely-in-canal* hearing aids are nearly hidden in the ear canal.

Both types are used for mild to moderately severe hearing loss. Because they are small, canal aids they may be difficult for a person to adjust and remove. In addition, canal aids have less space available for batteries and additional devices. They are not recommended for young children or for people with severe to profound hearing loss.

RITE: *receiver-in-the-ear* hearing aids are a new style of the Open Fit-mini BTE. RITE hearing aids take receiver or speaker out of the behind the ear portion of the aids and place the receiver directly in the ear canal. The two pieces are connected by a very thin wire encased in plastic tubing. The placement of the receiver in the ear canal tends to enhance natural sound quality. These types of aids may have a custom or standard ear piece.

CROS/BICROS: CROS hearing aid is an option for people who have normal hearing in one ear, and very little or no hearing in the other ear. A BICROS hearing aid is an option for the people with little or no hearing in one ear and a hearing loss in other. The hearing aid is worn on the ear with better hearing and an additional microphone is worn on the poor ear. This allows the person to pick up sound on the poor ear side and hear it on the better ear. The microphone picks up sound from the poor ear side and wirelessly transmits it to the hearing aid on the good side. These systems provide better sound awareness for sound occurring on the poor ear side.

Binaural hearing aid system comprises two complete electronic hearing aids, one for each ear of the user with the dominant ear tuned to recognize higher frequencies. The auditory signal from one side is delayed before be send to the brain, allowing the person to locate the sound s origins, and providing a sense of balance.

The three types are CROS (Contralateral Routing Of Signals), BICROS (Binaural Contralateral Routing Of Signals), and MultiCROS (Multiple Contralateral Routing Of Silyric investable hearing afghans).

A MultiCROS hearing aid is best when the user doesn’t want pick up noise from the bad or deaf ear, such as wind noise in a train.

Binaural hearing aids provide better understanding of speech in different (quit to noisy) situations, localization, better sound quality, and smoother tone quality with less distortion and better sound reproduction. They also provide a wider hearing range reduce feedback. Binaural hearing allows a quality of spaciousness or high fidelity to sounds, which cannot occur with monaural listening.

Invisible in canal hearing aids (IIC). This is because it fits deeper in canal than other types. Their deep placement in the ear canal gives a more natural experience of hearing. Unlike other hearing aids types, with IIC aid the ear is not blocked, occluded, by a large plastic shell. Some models allow the wearer to use a mobile phone and a remote control to alter memory and volume setting.

Extended wear hearing aids are hearing instruments that are non-surgically placed in the ear canal by a hearing professional. The extended wear hearing aid represents the first „invisible“ hearing instrument, very small, 16 mm long and available in a variety of sizes.. These instruments are worn 1-3 months at a time without removal. The instrument uses analog sound processing for high fidelity, and optimum power efficiency, enabled extended battery life. The device is digitally programmable and can be programmed by the clinician via a non-contact programming wand. Users can change volume and settings without the aid of a hearing professional.

III. PROCESSING

Every electronic hearing aid has at minimum a microphone, electronic circuitry, loudspeaker (receiver), and battery. There are three categories the circuitry based on the type of audio processing: analog or digital and the type of control circuitry: adjustable or programmable.

- Analog audio-adjustable control: The audio circuit is analog with electronic components that can be adjustable with small control. This type of circuitry is generally the least flexible.

- Analog audio-programmable control: The audio circuit is analog but with additional electronic control circuitry, that can be programmed, sometimes with more than one program. The user can change the program for different listening environment by pressing buttons either on the device itself or on a remote control or in the additional simple adjustable controls The digital electronic control circuitry was used to indentify and automatically reduce noise in individual frequency channels of the analog audio circuits. There are in this group excellent high fidelity hearing aids.

- Digital audio-programmable control: Both the audio circuit and the additional control circuit are fully digital. Fully digital circuitry allows implementation of many additional features no possible with analog circuitry, can be used in all styles of hearing aids and is the most flexible. Digital hearing aids can be programmed with multiple programs than can be invoked by the user or that operate automatically and adaptively. These programs reduce acoustic feedback, reduce background noise, detect and automatically accommodate different listening environments: loud vs. soft, speech vs. music, quit vs. noisy, control additional components such as multiple microphones to improve spatial hearing, transpose frequencies and implement many other features. Digital circuitry also allows control over wireless transmission capability for both the audio and the control circuitry. Audio signal can be sent wirelessly to and from external devices through a separate module, called a streamer that allows wireless connection to yet other external devices.

IV. MUSIC AND SPEECH

Although modern digital hearing aids can help hearing-impaired person enjoy listening to music, professional musicians and professional in the music industry understand what they need to hear and if have hearing aids they can learn to operate hearing aid fitting software.

Sound is generally characterized by pitch-frequency, loudness-intensity and quality-frequency spectrum. Sound quality or timbre describes those characteristic of sound which allow the ear to distinguish sounds which have the same pitch and loudness. Timbre is mainly determined by the harmonic contend of sound and the dynamic characteristic of the sound such as vibrato and attack-decay envelope of the sound.

Music vs. Speech: Music and speech have many differences, but the primary one is that music is more intense than speech. Overdriving the input stages of hearing aids can result in distorted sound. When comparing music to speech there are following essential differences: the long term spectrum of music vs. speech; differing overall intensities-dynamic; crest factor; differing frequency response.

Long-term music spectrum vs. long-term speech spectrum: The speech has a relatively well-defined and uniform long-term speech spectrum regardless of the language spoken. All speech derives from the human vocal track. Sound resonances (formants) are generated by well-defined quarter wavelength resonators and so on. The resulting long-term speech spectrum is well defined and can be use in the development of a target for amplified speech. Speech tends to have its greatest intensity in the lower frequency ranges, with the higher frequency fricatives being of lower intensity. This has been used to set parameters for gain, compression, and for hearing aid quality control testing. Music can derive from many sources, such as the vocal tract, a percussive instrument, and many of instruments that are stringed (piano, violin, guitar...) with rich harmonic structure, woodwind or brass instruments. These can be amplified or unamplified. Depending on the music, it may be of low intensity or of high intensity. And, depending of the instrument the music spectrum may be high –or low frequency in emphasis.

Unlike speech, music is highly variable and a goal of a long-term spectrum is poorly conceived. There is simply no music target as there is for amplified speech.

Differing overall intensities: Speech has average 65 dB SPL +/-12-15 dB. Speech rarely exceeds much greater than 90 dB. Slithered are quite good estimates of soft speech, medium speech and loud speech which are used to set hearing aids. Dynamic range of the speech is approximate 30-35 dB. In contrast, depending on the music played, various instruments can generate very soft sound 20-30 dB SPL to amplified guitar and brass in excess of 120 dB SPL. The dynamic range of music as an input to a hearings aid is therefore on the order 100 dB, versus only 30 – 35 dB for speech. Overall, when played at an average or mezzo forte level, classical music at the player’s ear can be typically 85-100 dB SPL. Rock, pop,

and jazz music, on average, tends to be 10 – 15 dB louder or more intense. The dynamic range of music as an input to a hearing aid is therefore on the order of 100 dB vs. only 30-35 dB for speech.

Crest factor: Crest factor is the ratio between peak level and average (RMS) level. Speech has a fairly consistent crest factor of 12 dB, while music has a crest factor of up to 18-20 dB for many instrument. This acoustic characteristic is very important for the dynamic impact of music. Compressor circuitry and hearing aid test systems use these data. Compression systems and detectors based on peak sound pressure levels may have different operating characteristics for music as input to a hearing aid than for speech. From that, it is quite easy to see why these signals must be processed differently within the hearing aid. That is, music may cause compression systems to enter the non-linear regime at lower intensity than would be appropriate for that individual.

Frequency range: A sound engineer or a musician needs to be able to hear all of the musical pitches in precise balance. It is important to known that every octave has 12 notes. There are just as many notes between 64 Hz and 128 Hz, as there are between 880 Hz and 1760 Hz.

High fidelity describes audio systems that faithfully reproduce the original sound. Such systems must have a low noise levels (SNR), a low distortion level (total harmonic distortion less than 1%), appropriate dynamic and frequency range, and do not alter frequency content of the original signal. Using such criteria, one would not expect hearing aids to be high-fidelity since they purposely shape the spectral and dynamic input to compensate for the herring loss their users.

For speech, the most important spectral range is about 1000 Hz. 74 % of frequency content important for speech intelligibility is located at or above 1000 Hz (AI). Frequency spectrum of speech is from 100 Hz to 12 kHz.

It is well known that a wide frequency range contributes to the perceived naturalness of music and of speech too. Music has spectrum from 20 Hz to 20 kHz. However, the fundamental frequencies which define the pitch are laying in range from about 20 Hz to 4200 Hz. The fundamental frequency of the lowest note of an 88-key piano is 27.5 Hz. The lowest note of a double bass has a fundamental frequency of 41.2 Hz, while a guitar has a fundamental frequency of the lowest tone 82.4 Hz. However, the fundamental is often important for hearing the balance of one note against another, as well as for hearing the naturalness, warmth and fullness of low-pitch notes. For example, 63 keys (about 72 %) of a piano keyboard have pitches whose fundamental frequencies are bellow 1000 Hz, as well as many of their higher harmonics. Human singing voice has almost all fundamental frequencies of the pitches bellow 1000 Hz.

However, the highest *C* note on a piano or piccolo flute is 4186 Hz, while highest note *C* on a violin is 2093 Hz. The highest pitch, a soprano voice has fundamental frequency 1046.5 Hz (*C*6).

Sustained tones and percussion of music can be considered as the correlates of vowels and consonants in speech. With speech, vocal tract resonances-formant ranges-, which occur at frequencies well above the fundamental frequency of a voice, help the listener to distinguish one vowel from another. Similarly, resonances occurring above the fundamental frequency of musical tones help the listener to distinguish the sound of one instrument from another.

Generally, the highest important vowel formant is about 3000 Hz. Singing voice harmonics and speech overtones extend much higher. For example, the violin has significant harmonics and overtones above 12 kHz, and some musical instruments have harmonics and overtones above 17 kHz. Conductors, musicians and sound engineers need to be able to hear all of music pitches and sound components in precise balance.

V. LIVE MUSIC QUALITY

Starting from these discussions of the differences between speech and music, it is quite easy to see why these signals must be processed differently within the hearing aid. Now we well explore the following systems that are implemented to improve live music sound quality. These differences between physical property of speech and music can now serve as the basis for differing electro acoustic getting a hearing aid for input of speech vs. music.

The music program or a set of optimal electro acoustic parameters to listening music would include:

- A sufficiently high peak input limiting level ensuring that more intense components of music are not distorted and the front end of the hearing aid.
- Either a single channel or a multiple channels system in which all channels are set for similar compression ratios and knee points
- An RMS detector processor compression circuitry with a knee point set to engage at input 5-8 dB higher if the hearing aid uses a peak compression detector.
- A disabled feedback reduction system, or a feedback reduction system that uses gain reduction or a phase feedback cancellation
- A disabled noise reduction circuit, although because of long attack times and short release times, this circuit may rarely be activated for many form of music.

VI. TESTING OF HEARING ABILITIES

In performance of music, an almost perfection is needed, in recording a maximum quality; recording studios, concert halls, control rooms and project studios must satisfy high criteria. While equipment for recording, processing, transmitting and reproduction of sound is more and smarter and improved, recording techniques are more complex and finished recordings are more various.

Audiophiles and other music lovers consume music as a way of entertainment. A question is raised on the persons who are exposed to music professionally, such as musicians, recording engineers, DJ- s, which are all in many cases exposed to high sound levels. It is shown that those professionals may have significant hearing

impairments, and hearing is very important for their profession. They average age is 45 years.

Within those professionals, several groups can be recognized: musicians, recording engineers, sound engineers, sound technicians, and DJ-s. Clearly here are also a number of subgroups, depending of exposure to different sound levels: classical musicians, pop and rock musicians, recording staff in live performances or in recording studios.

The testing approach was as follows: the hearing was tested for all examinees and their audiograms were recorded. Three characteristic audiograms with visible hearing losses were extracted, while other examinees had normal hearing. The question was raised of the needed characteristics of the hearing aids, which would enable the examinees to properly fulfill their professional duties.

For this examination we prepared an analogue hearing aid, which was consisted of studio amplifiers, devices and programs for the processing of analogue and digital signals, studio headphones (two different types) and loudspeakers, studio equipment for the recording and reproduction of music, and DAW. Such an audio system enables fairly good processing, adjustment and correction of the hearing according to the audiogram for each examinee suffering from hearing loss. The results of the examination are obtained by the comparison of the listening or recording of a particular program with above-mentioned «analogue hearing aid» - an audio system and with binaural digital hearing aids. Applied hearing aids were two types of high-quality digital aids, primarily indented for speech, although their manufacturer's data do not exclude the music. The examinations were performed in two different quiet listening rooms with reverberation time 1 s and 0.65 s. The objective characteristics of the systems were recorded, and the measurement results showed that the devices and components are of high quality.

A. THE EXAMINATION PROCEDURE

The eight subjects, (three sound engineers and five musicians) were tested. The four of them suffered from hearing loss, two mild and two moderate. The other four had normal hearing.

Recordings of different kind of music were chosen: classical, jazz, pop, rock, all in different performances. In listening, the first task was to evaluate the quality using arranged audio system, and the second task was the evaluation using hearing aids. The examinations were carried binaurally and stereophonically, A-B comparison.

Subsequently, the recordings of particular musical instruments were captured: accordion, clarinet, piano, double bass, voice and quintet. Afterwards, the evaluation of the recordings was performed, comparing hearing tests with the audio system and with the hearing aids. Some of the examinees suffered from hearing loss, while the others have normal hearing.

In evaluation of the quality, the parameters used in architectural acoustics and evaluations of acoustical transducers were applied. More over, some descriptive parameters were introduced, as well as parameters suitable for the evaluation of hearing aids. Here are listed some of them: definition or clarity, speed of successive tones, intimacy or presence, liveliness at mid-frequencies, spaciousness, warmth, strength of sound and loudness, timbre and tone color. Brilliance, balance, blend, ensemble, attack, texture, dynamic range and noise, distortion, summary of the musical qualities affected by hearing.

All additions were A-B type comparing the evaluating hearing aids with the reference „analogue hearing aid“, which is programmable, and sounds very good to excellent. We played a musical passage with the evaluating hearing aids and then the reference, repeating until we can identify the differences.

Some listening parameters are further added in listening tests: Does the composition sound realistic? What is with rhythm and pace? And micro and macro dynamics; Are transient spikes rendered cleanly and clearly? Does the attack and decay of transients sound natural? Does the music sound smeared and frozen?

In recording, a test was conducted in which five (5) musicians and three sound engineers were asked to rate how the music they played and recorded sounded to them in three situations: using hearing aids, through audio system with headphones and with loudspeakers.

The attribute scales used with the subject were based on the perceptual dimension of sound quality judgment:

Loudness: Loud vs. Faint

Fullness: Full vs. Thin

Crispness: Crisp vs. Blurred

Naturalness: True to the sources vs. Artificial

Overall fidelity: Wide dynamic vs. Limited and compressed

Overall fidelity with audio system was judged as substantially better than with hearing aids. A musical program with audio system was judged significantly fuller than with both hearing aids. The fidelity to the input signals (different music programs and different instruments) significantly lacks naturalness among two hearings aids due to a large variance in the signals. However, it was found significantly better with the audio system. Also, there were clear differences in the results for the other three attributes: fullness, overall fidelity, and naturalness.

The result for loudness and crispness revealed significant difference between audio system and one hearing aid pair, and smaller difference comparing to the second pair.

The fidelity to the input signal can be seen by distortion when playing musical instruments at higher sound levels. Although hearing aids are not intended for the quality listening of music, sound engineers with hearing losses, which applied hearing aids at recording sessions, made somewhat better recordings. Testing with other afore-mentioned parameters leads towards practically same conclusions.

Since the number of the examinees was relatively low, the results are not shown in a tabular form. However, the

further testing are conducted with an enlarged number of examinees and different hearing aids.

VII. LIVE MUSIC PLUS

Today there are many programs for live music, for example, *Live Music Plus*. The four systems that Live music plus is consisted from are as follows: Live music processor; Channel Free Compression; wideband frequency response, and microphone setting. Live Music Plus combines four elements to present live music signals accurately and enhance the experience of music for hearing aid users: Live Music Processing to preserve the dynamic characteristics of music; Channel Free processing to amplify music accurately so that is within users s dynamic range; A wideband frequency response to help make the music natural, and musicians; A fixed directional setting to focus the performing.

Requirements for High Fidelity Hearing Aids:

- In a digital hearing aid, the input stage includes microphone with preamplifier and the analog-to-digital converter (ADC). Each of these components affects the integrity of the input signal.
- Microphone: Of relevance here is its bandwidth, the noise floor, its directional sensitivity, and saturation level. Bandwidth of today s microphones is typically broad. However, this may not be as desirable. The very low frequencies, although inaudible to the users, may saturate the microphone. The theoretical limit is 115 dB. A microphone is also judged by its polar pattern. Besides typical polar pattern, can use of automatic directional microphones.
- Sampling frequency: For high fidelity processing it is necessary to sample at s higher frequency than 16 kHz because a significant amount of speech and music i is available above 8 kHz. Sampling frequency must be 32 kHz.
- Quantization: To avoid saturation at the input stage from loud sounds, one can do two things:1) Increase the number of bits (20 to 24 bits) of the ADC. This is achieved at the expense of increasing and power consumption. 2) Place a compression limiter at the input stage-Doing so will reduce the saturation distortion without additional power consumption, Both approach taken by many manufactures.
- Processing: Hearing aids perform constructive distortion. That is, they alter input sounds so they can be audible and intelligible to the user in as many environments as possible. Frequency shaping compensates for the differential loss. Compression compensates for the change in loudness growth function etc. Need has little delay times, and phase distortion.
- Slow acting WDRC: One processing algorithm that is active at all input levels is compression. A long attack and release time this compressor, which means that the attack time is longer than 20 ms and the release time longer than 1 s. Better solution is the use an adaptive compression system.
- Output stage: Hearing aids have miniature amplifier-loudspeaker systems. The bandwidth of the receiver-loudspeaker limits the frequency range the hearing aid. Typically, a BTE hearing aid receiver has a bandwidth from 300-400Hz to 6 kHz, while a custom ITE may extend to 8 kHz. Recently hearing aids receivers extend beyond 10 kHz. We need frequency response at least 80 Hz to 115 kHz pr better as FM radio 30 Hz to 15 kHz.
- Output limiting: Most modern digital hearing aids use a compression limiter at the output stage to prevent saturation distortion. Equalizer band - inserting appropriate equalizer. More channels EQ bands with bandwidths 1/3octtaves or critical bands, or parametric equalizers.

VIII. WIDENING MUSIC WITH VIRTUAL SOUND SOURCES

For many people listening to music is an important part of life. Most often the music is recorded and played on a CD-player, DVD-player, the radio, the television, an mp3 player, or a computer. Listening to music from such devices was long out of reach for hearing aids users. But recently, the development of devices, such as the *Streamer*, that can send music wirelessly to hearing aids enables people to enjoy listening to music directly in their hearing aids with a good SNR (signal to noise ratio). However, listening to music sent directly to hearing aids is not optimal. The sound image appears to be inside the listener's head. In reality, for different kinds of signals the listener perceives sound image from different directions. When the signal is always the same it as being in the middle of hears. When the stereophonic signal is perceived as being on a line between the ears, by changing the level of the signal in either ear, the sound can be moved between the ears- lateralization of the sound image.

Since recording music is intended to be listened through loudspeakers in a room, it is desirable to simulate this when listening through hearing aids. This can be done by filtering the hearing aids signals. Binaural synthesis has been used in developing a new algorithm *Music Widening*, which is implemented in some new types of wireless hearing aids.

A Virtual Environment and the Widening Algorithm: very important in binaural synthesis is that the sound pressure at the listener's eardrums contains all acoustical information abound the sound event, including spatial aspects. When sound is played, the incoming sound wave interacts with the torso, head and pinnate of the listener before entering ear canals. This interaction can be described by the head related transfer funcion-HRTFs. HRTFs can be used to create virtual sound sources. This is done by filtering a signal with left-right pair of HRTFs from certain direction. When the resulting left and right signals are played through hearing aids, the listener perceived the sound as coming from a point in space that correspond to the chosen direction.

In the simulation described afore there are no room reflections. However, to simulate a loudspeaker in a reflective, real environment, the characteristics of the room and positions of the sound sources, and listener in the room must be available. In general, a room impulse response can be divided in three: the direct sound, early reflections, and reverberation-late reflections. In binaural synthesis, the room impulse response is combined with HRTFs to simulate a virtual sound source in room. That means, binaural synthesis can be used in create an auditory virtual environment. The advantage of this approach over other methods of sound reproduction is that the listener has the experience of being in the virtual environment. This allows the listener to use the full potential of his auditory system in everyday life. The *Music Widening Algorithm* gives the listener a spacious and pleasant sound image when listening to music through the aid streamer. The *Music Widening algorithm* has many adjustable parameters including the direction and distance to the sound source. The room size and distances to the walls can also be adjusted. The absorption properties of the walls can be changed, and one can set the number of reflection to implement in the hearing aids (reverberation time). All these parameters were fine-tuned to find the optimal balance between spatial perception and processing resources. Since the preferences potentially depended on the signals: speech or music, many signals were used for fine-tuning. By optimizing all room parameters, the final left and right impulse responses implemented in the hearing aids were selected and the parameters were fixed. The therapist can adjust the overall level of the reflections in accordance with a patient's individual preferences. The *Music Widening algorithm* was developed to improve the poor sound image that can result from listening to music that is streamed directly to hearing aids. A simple mirror-image model of a room is used to calculate the contributions of the direct sound and the room reflections. By replacing each contribution with a virtual sound source, it is possible to create the impression of sound sources in a simulated room. This sound image is perceived to be outside the head. The results from the listening tests indicate that applying this processing to a streamed music signal can greatly improve the spatial impression.

IX. CONCLUSIONS

Hearing aid manufacturers desire to maintain and increase sound quality through advanced technology and innovation. High fidelity hearing aids compared to normal hearing aids involve in the design and adjustment follow characteristic: The hearing aid must not introduce unwanted changes to the signal reaching that eardrum; the signal hast to be processed to compensate perceptive distortion created by the hearing impairment; the processing needs to be adjusted to the individual hearing impairment of each user (frequency response shaping, dynamic range, etc.). Recently, spatially binaural processing has become commercially available. These high-fidelity hearing aids are useful for children and disabled people, and DSP for people with a cochlear implant.

Based on the described test results, hearing aids were built for two examinees with very satisfying results.

X. ACKNOWLEDGMENT

USB RF Front-End of the DRM Receiver Under LabView API Environment

D. Šoštarić, D.Vinko and T. Švedek
Department of Communications, Faculty of Electrical Engineering, Osijek, Croatia
e-mail: dvinko@etfos.hr

Abstract – DRM (Digital Radio Mondiale) system uses software decoding what enables simpler RF front-end. DRM signal is a digital signal for radio broadcast on frequency bands below 30 MHz. The proposed USB RF front-end is designed to work with existing DRM software which uses soundcard as ADC between RF front-end and DRM decoding software. DAC of the decoded digital signal and audio reproduction is realized by PC integrated soundcard, while PWM (Pulse Width Modulation) used for frequency control of local oscillator uses DAC on external USB soundcard. In order to have a single software application, the existing DRM software is embedded in LabView environment which is developed for RF front-end control.

I. INTRODUCTION

DRM (Digital Radio Mondiale) system [1] is a radio diffusion broadcasting system that occupies frequency bands below 30 MHz. Its main advantage compared to present AM radio diffusion is better quality of received transmission due to digital encoding. It has been shown [2] that coexistence of DRM system and current analog AM broadcast is possible and that their coexistence on same frequency does not impose any significant negative effects.

With development of DRM system, a part of the receiver is replaced by software. The demodulation and decoding process is fully implemented in software. This enables simpler design of RF frond-end of the receiver. The simplest and fully functional solution for the RF front-end is homodyne receiver structure shown in Figure 1. By using homodyne structure, the hardware part of receiver consist of only a local oscillator and mixer circuit, since the decoding is done by software.

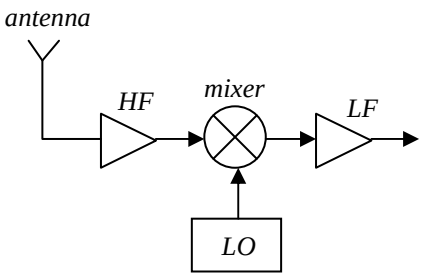

Figure 1. Homodyne receiver structure

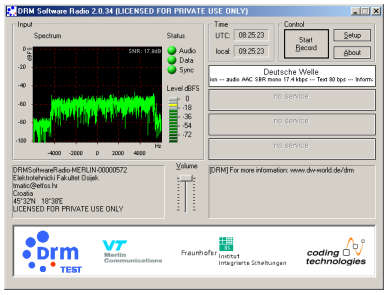
This work was supported by the Ministry of Science, Education and Sports of the Republic of Croatia under project 165-0361630-3049.

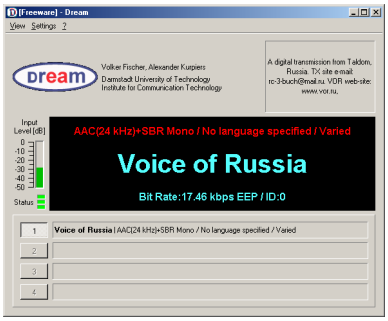
Currently available software that is used to decode DRM signal uses soundcard microphone input to sample and decode digital data. This works fine for research purposes, but poses a problem for development of a user friendly receiver. Simple USB plug'n'play device would be the most desirable solution, but then a new software would have to be designed to accommodate DRM signal decoding through USB port instead of a soundcard input. We propose a new concept of USB RF front-end of a DRM receiver with developed LabView application. To successfully implement RF front-end of DRM receiver under single USB device, without the need to design new decoding software, an external USB soundcard is used.

II. DRM SOFTWARE

Software packages [3],[4] designed for DRM signal decoding and reproduction use the analog-digital conversion built in microphone input or "line in" input on PC soundcard. With sample rate of 48 kHz the soundcard offers sufficient hardware power to sample the 12 kHz DRM signal in it's base band spectrum. Figure 2. shows two most commonly used DRM software packages.



a)



b)

Figure 2. a) DRMSoftware Radio and b) DREAM software packages

As mentioned before, both software packages shown in Figure 2. are using soundcard input for analog to digital conversion (ADC) of baseband DRM signal. This is a restriction that dictates the design of receivers hardware part, that is the RF front-end of the DRM receiver. In our past work [5] we have designed DRM receiver compatible with both software packages. The design and the drawbacks of such solution are discussed in next section.

III. RF FRONT-END OF DRM RECEIVER

Figure 3. shows the block diagrams of the RF front-end of the DRM receiver. It can be seen that is requires multiple connections to computer. The design could accommodate versatile measurements but was not user-friendly.

The receiver consists of HF amplifier, DDS circuit and frequency mixer circuit. High frequency amplifier is used to amplify signal from antenna, since for compact device antenna dimensions are significantly smaller than regular antennas used in those frequency band which vary from 2.5 m to 40 m. Also, with large frequency span of the DRM system ranging from 1 MHz to 30 MHz for majority of transmitters, the HF amplifier must have a wide bandwidth. With amplifier the gain of the received signal is sufficient for successful decoding.

DDS (Direct Digital Synthesis) circuit is used as local oscilator and is computer controlled through RS232 port. Usage of DDS circuit enables very precise frequency setting which can be adjusted in steps of 1 kHz throughout whole frequency band.

Frequency mixer circuit is used for separation of useful DRM signal from carrier frequency. Received signal is then fed into soundcard, where the decoding software [2],[3] takes on to extract the transmitted radio signal and data stream if any data is transmitted together with radio broadcast.

Since the presented RF front-end of DRM receiver uses 5 V as power supply, the third cable connected to the computer was USB connection which was used only for powering purposes. Together with short vertical antenna connected to the receiver the overall solution is not to practical for end user.

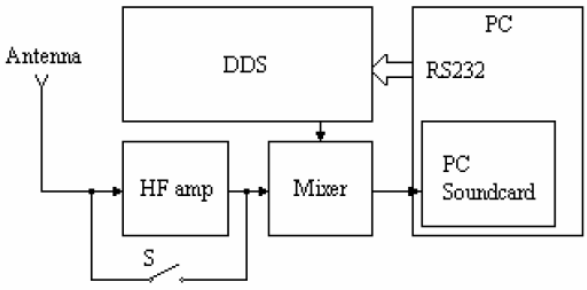


Figure 3. Previous version of RF front-end of DRM receiver

IV. PROPOSED CONCEPT

The new proposed concept for RF front-end of DRM receiver uses the benefits of existing USB sound cards. The common design of a USB soundcard is given in Figure 4. The design is compact and it has “line in” and “line out” connectors provided opposite from USB port.

Figure 4. Standard USB sound card

To use the external USB soundcard to it’s full extend, the proposed concept for DRM receiver is given in Figure 5.

Proposed DRM receiver consists of a additional electronic circuit that can be simply plugged into external USB sound card and it uses both “line in” and “line out” connectors. The added electronic circuit is a homodyne receiver as shown in Figure 1. The three main building block of a homodyne receiver correspond to block diagram in Figure 3. with one significant difference. In Section 3. where the design of DRM front-end is discussed a RS232 port is used for DDS circuit control. This is omitted in this new proposed receiver. Tendency to design a user-oriented device does not allow the usage of numerous connections to the PC. Furthermore, RS232 port is nowadays rarely available on both desktop and laptop computers. Instead of serial communication by RS232 protocol a different solution must be used to control the frequency of local oscillator.

With available external USB sound card whose “line in” connection is used to send received signal to the decoding software, remaining “line out” port can be used to control the frequency of the local oscillator on the DRM receiver.

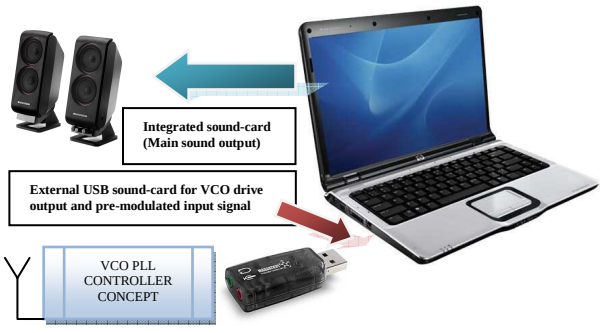

Figure 5. Proposed concept of RF front-end of DRM receiver

To change the frequency of the local oscilator through “line out” of the sound card the developed LabView application is used and is in detail explained in section 5.

Here is important to say that through LabView application a PWM (Pulse Width Modulation) signal can be sent to the “line out” of the sound card and this PWM signal can be used to control the frequency of local oscillator. To accomplish this, a local oscillator design must be PWM controlled with wide frequency span and sufficiently small step. This is a part of the future work since in this paper we propose the concept of the receiver with developed LabView application for external USB soundcard “line out” control.

With “line out” of the external USB soundcard being used for frequency control, it can not be used for reproduction of decoded DRM signal. Therefore, the internal soundcard of the computer must be used for radio broadcast reproduction. This is actually a simpler solution for end user since no additional setup is required to listen to decoded DRM radio signal.

V. LABVIEW ENVIRONMENT WITH API INTEGRATION

The LabView system consists of the API (Application programming interface) and number of associated files. Main extensions for program are called *virtual instruments (VIs)* because their appearance and operation imitate actual instruments. LabView is a program development application, much like various commercial C or BASIC development systems, or National Instruments LabWindows. However, LabView is different from those applications in one important respect. Other programming systems use *text-based* languages to create lines of code, while LabView uses a *graphical* programming language, *G*, to create programs in block diagram form. LabView uses terminology, icons, and ideas familiar to scientists and engineers and relies on graphical symbols rather than textual language to describe programming actions [6]. Interface advantage is that has extensive libraries of functions and subroutines for most programming tasks. Also, includes conventional program development tools, so we can set breakpoints, animate program execution to see how data passes through the program, and single-step through the program to make debugging and program development easier.

LabView is graphical oriented programming language which means that API is realized through special tool under *Front Panel* interface. Each *Front Panel* has an accompanying *Block Diagram*, which is the *VI* equivalent of a program. Thus, each action in the *Front Panel* is manifested by graphical icons that is necessary to link in the *Block Diagram*.

LabView uses a floating *Tools palette*, which we can use to edit and debug VIs of API, Figure 6.

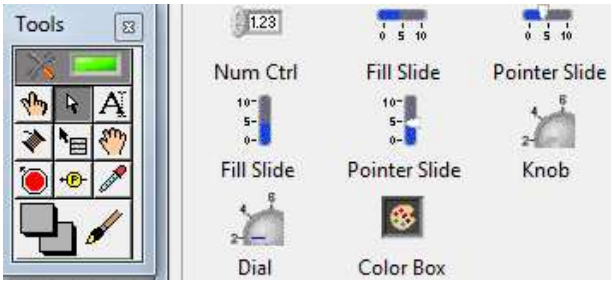

Figure 6. LabView Tools and Control palette

In order to realize applications for DRM USB RF Receiver Front-End, standard example is used to generate sound with different waveforms. Modifications are made that utilizes the only rectangular pulse mode with variable PWM duty cycle values, Figure 7. Thus, in the control box is set waveform type: square, while the block diagram shows graphic icon for duty cycle setup. USB sound card generates sound by setting the Device ID with value "0". Generated signal is passed on to the electronics, supported by hardware component of VCO (Voltage Controlled Oscillator) which changes oscillating frequency compared to imposed variable voltage input. Changing the frequency of the oscillator is allowed via a simple circular slide within the API. Station frequency is allowed to be manually changed with test interface through circular slide of the "Frequency" and “Tuning Duty Cycle”. Processed information comes to the existing software interface integrated in LabVIEW API.

The following front panel; Figure 7. and appurtenant block diagram; Figure 8., represents a complete LabVIEW application. Chart diagram shows amplitude with early configured parameters of frequency and duty cycle. Block diagram consist of two application loops and error factor correction is supported through control line (wire). Internal recursive loop is based for square waveform and real-time duty cycle variable change.

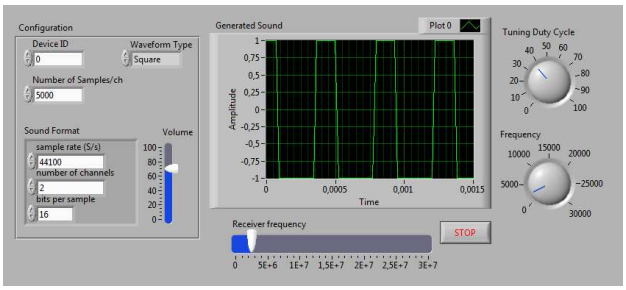

Figure 7. LabView application for tuning Duty Cycle from 0 – 100% and receiver frequency with predefined band (front panel)

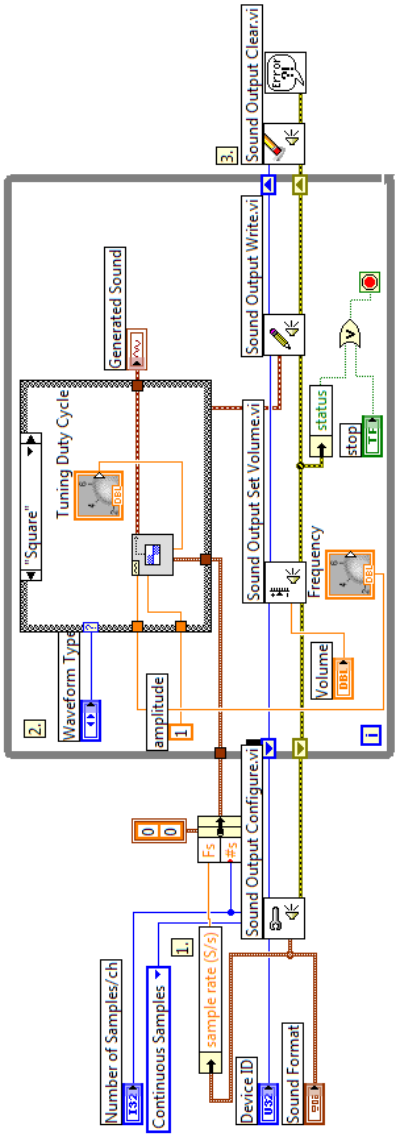

Figure 8. Block diagram of LabView application for tuning parameters

Integration of existing application for demodulating and reproducing the received signal was realized inside LabView interface using an additional "G" code. Predefined concept of integrating application was installation with automatic path on the HDD. Compiled application of DRM software with activation process was showed on Figure 9. Path: *"C:\Program Files\DRM Software Radio.exe"* in the final application is hidden and automatically executed.

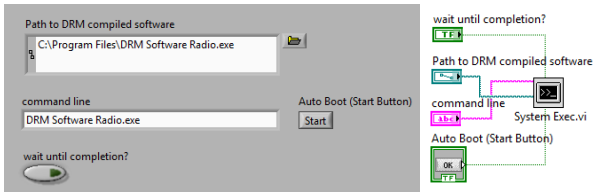

Figure 9. LabView application for *.exe file integration with specified path and block diagram of default command set

VI. CONLUSION

The concept for new RF front-end of DRM receiver is presented together with developed LabVIEW API. The existing demodulation software such as DRM Software Radio and DREAM can be easily implemented in developed API. This way, a uniform appearance of software part of DRM receiver is maintained.

The proposed concept uses market available USB soundcard which, together with voltage controlled oscillator and mixer circuit, forms a front-end of DRM receiver. Such implementation makes the design of the receiver simple and cost efficient. Also, LabView application is executable and does not require for an user to have LabView software package installed.

A VCO design which is controlled with PWM on USB soundcard is a part of the future work, which will give a functional front-end of the DRM receiver with here presented LabView application.

Verification Structures for Design of Video Processing Circuits

Andrej Trost[1] and Andrej Žemva[1,2]
[1]University of Ljubljana, Faculty of Electrical Engineering, Ljubljana, Slovenia
[2]CO Namaste, Ljubljana, Slovenia
Andrej.Trost@fe.uni-lj.si

Abstract - In the paper we present generic simulation test benches and test structures for the verification of the video processing circuits. The test benches accelerate simulation of the digital video frames in an ITU-R BT656 video format and a standard computer VGA format, which are most commonly used in our applications. The acceleration is achieved by selective stimuli in the area of the interest and selective collection of simulation results. We also present a custom FPGA based development system supporting both video formats. Several test structures were designed providing debug control and data for effective hardware verification. A video processing design case study is presented. With the presented verification methodology we are able to accelerate the design process of video processing circuits. The benefit of our approach is that it can be used with the standard programmable design tools and low cost platforms, since we do not require special software or hardware emulators. The approach can be used for the research or educational purpose.

I. INTRODUCTION

Video and image processing applications are moving from the computer based systems to small embedded platforms. Application specific graphics processors used in computers generally do not meet design constraints of embedded applications concerning size, cost and power consumption. The advances of technology enable single System-on-Chip video processing solutions [1]. Video processing in real-time requires a digital signal processor (DSP) or an application specific integrated circuit (ASIC) for hardware acceleration of the specific tasks [2].

Due to the high costs of development and production of the ASICs, programmable devices, especially Field Programmable Gate Arrays (FPGA), are the preferred technology for rapid development and prototyping. Smaller FPGA devices are suitable for video encoding, mixing and simple graphics routines. The high-end devices can be used for high performance video processing [3,4].

The circuit design tools enable high-level behavioral or register-level digital circuit description in hardware description languages VHDL or Verilog. This is a common design entry method for the programmable devices and the ASIC technology and is a part of contemporary digital design courses [5]. The design and verification of video applications in hardware is more demanding and time consuming comparing to software implementation [6]. There are often cases where the designer should observe several frames of processed video in order to analyze the result and the amount of data can be a serious obstacle to perform thorough simulation or hardware verification. As a consequence, only a fraction of the video sequence or a single frame is typically verified by simulation and hardware verification is performed on a time consuming trial and error basis.

Programmable devices are extensively used as logic emulators for rapid prototyping and hardware verification of digital circuits running in real-time or at least much faster than circuit simulators. The main drawback of circuit emulation is that it is difficult to observe internal signals during circuit debugging. A typical design verification method consists of partial simulation of circuit components and final verification on circuit emulator [7].

One approach to handle the video processing design complexity is automatic circuit synthesis from algorithm description in a language similar to classical programming languages [8], but these tools are still limited and expensive. Another approach is development of effective verification structures incorporated in the classical design cycle [9,10].

In the paper we present design of generic test benches for effective simulation of typical embedded video processing circuits and test structures for hardware verification on the programmable circuit emulators.

II. DESIGN OF DIGITAL VIDEO PROCESSING CIRCUITS

Figure 1 presents typical blocks of a digital video processing system. Essential component of any video processing system is a timing generator which produces control signals with exact timing for the video data flow. The input component is either a video decoder or a frame buffer used as a pixel data source. The output encoder or modulator provides final formatting of the video stream. These blocks can be IP (Intelectual Property) components designed once and reused on several video processing circuit implementations.

The core of the system is a graphics engine performing video processing algorithms. The video processing circuit design effort is concentrated on this component, where most of the application specific functionality is implemented.

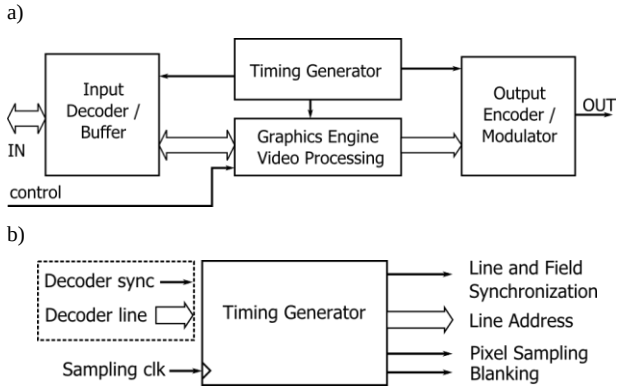

Figure 1. Digital video processing System-on-Chip
a) typical building blocks
b) timing generator details

Timing of the video data stream depends on the video scanning standards which can be divided into progressive and interlaced. The data stream is composed of lines of consecutive pixels and blanking intervals. Figure 2 presents position of pixel fields in interlaced PAL video and frames in progressive computer VGA scan [11].

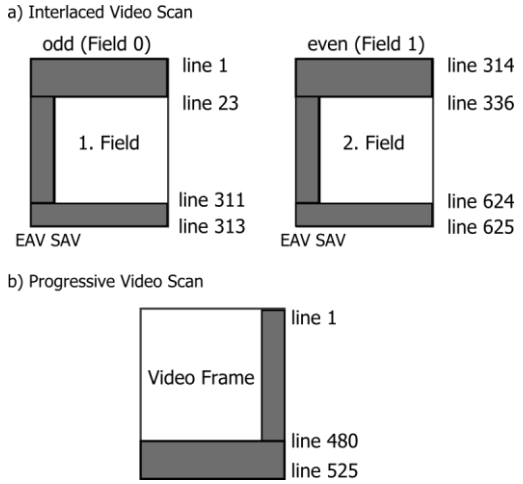

Figure 2. Pixel data and blank position in a) interlaced (e.g. PAL) and b) progressive video scan (e.g. VGA)

Line synchronization pulses are active during video blank interval and they provide a reference for start of active video data (SAV) scan, as presented in Figure 3. The current line is sampled until the end of active video (EAV). Video sampling frequency in PAL ITU-R BT656 format is 13.5 MHz for luminance signal and 6.75 MHz for each color-difference signal. The multiplexed video data stream clock rate is 27 MHz and the standard computer VGA clock is 25.175 MHz.

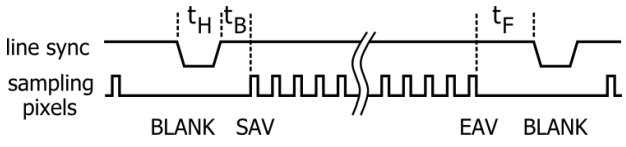

Figure 3. Characteristic timing of a video line

A digitized PAL active video line has 1440 sampled data words and a line in basic VGA mode has 640 RGB words. These numbers do not include blanking time and a multiplier of sampling frequency is used for image processing operations. As a consequence millions of cycles and signal transactions are executed in the simulation of one video frame and typically only a few frames can be practically tested on the circuit simulator.

Image processing algorithms based on pixel or local neighborhood operators can be effectively tested on a few lines of data, but the global operators and graphics engines require testing on several frames. Small graphics engines use single image buffer which is updated during blanking intervals thus avoiding expensive high speed multiple image buffers. We will present a verification method which accelerates simulation of such engine.

A. Verification Test Bench for Graphics Engine

The test bench simulates behavior of front and back end of video processing system and provides all the control signals of the timing generator. Figure 4 shows main VHDL processes and connections in the test bench. If the test requires input image, we include XML data read process. A test grayscale image is first converted into ASCII format PGM and then translated into XML format which can be read by the test bench. Translation is performed by simply adding XML tags into PGM header as presented in Table 1.

TABLE I. IMAGE CODING IN PGM AND XML FORMAT

Element	PGM	XML
Header Type	P2	<?xml version=”1.0”?>
Header Comment	# CREATOR	<img>
Header Size	256 256	<dim>256 256</dim>
Data Pixels	172 173…	<pix>172 173 …
End		</pix></img>

Generic timing process produces timing signals depending on the simulation setup parameters. The output of this process simulates all the characteristic events of video timing: start of video line, horizontal and vertical blanking, but the amount of active video and blanking cycles can be greatly reduced. It is often sufficient to simulate and observe a small window in a video frame, for example a window of 32 lines by 64 pixels to test the operation of the video engine. The simulator executes 2k cycles instead of 416k cycles which results in over 200 times simulation speed-up.

The test bench is designed generically in order to be reused by different video processing applications. Generic VHDL parameters include: graphics timing in terms of clock cycles and coordinates of observation window. A design specific stimulus should be included in the specific control process.

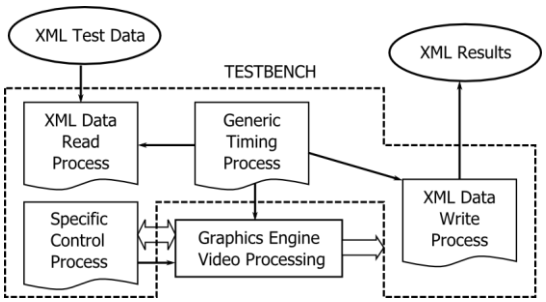

Figure 4. Generic simulation test bench

The XML data write process captures windows in video frames and saves them in XML file. We developed a web page for easy visual inspection of the output pixels in the captured windows. A JavaScript code loads XML data file and displays magnified window pixels of the selected frame. Figure 5 presents an example of visualization that was part of testing a VGA graphics engine executing a Pacman game. The presented test bench with visualization support in the simulation phase supports early debugging and can significantly shorten the HDL based design cycle.

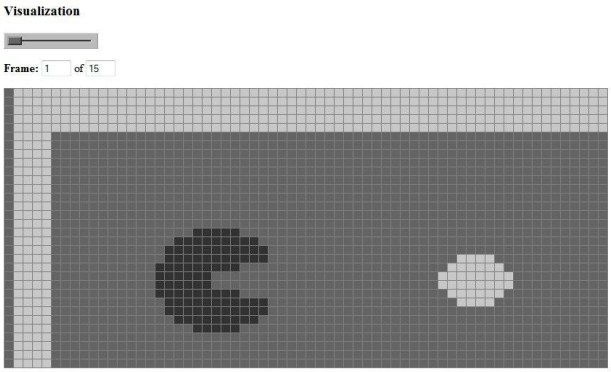

Figure 5. Visualisation of the test benh results

III. VIDEO PROCESSING DEVELOPMENT SYSTEM

Our video development system is composed of an FPGA board with Xilinx Spartan-3 XC3S400 and a video interface board as shown in Figure 6. The FPGA device XC3S400 has 8064 4-input look-up tables and D flip-flops, 288k bits of block memory and 16 hardware multiplication units used for digital signal processing. The emulated circuits are designed in VHDL and synthesized and implemented with the Xilinx design tools.

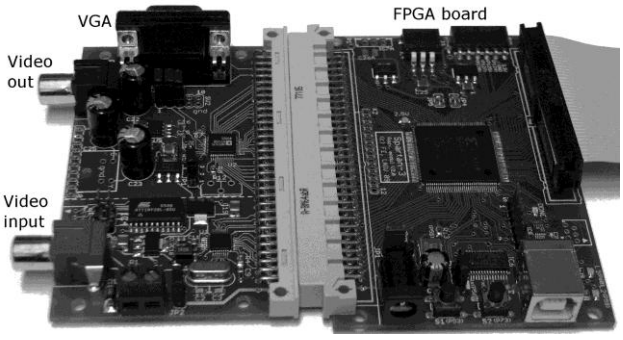

Figure 6. Programmable video processing development system

A. *Hardware Components of the Development System*

Figure 7 presents hardware components of the video processing system. Composite video signal, for example analog PAL video form camera, is fed to a video decoder circuit TVP5150A. The decoder output is 8-bit digital stream and a reference 27MHz clock signal. The input video stream is processed by the emulated circuit in the FPGA device. The circuit generates digital video output in the form of C and Y or R, G and B data streams connected to a fast three channel D/A converter ADV7125. The produced analog signals can be used directly as analog computer VGA or s-video signal. Composite video output requires additional reconstruction filter (MAX7453).

The FPGA prototyping board includes USB interface used for downloading the FPGA bit stream and debugging the designed circuit through virtual serial port. A parallel external bus is used for connection memory buffers or another FPGA emulator.

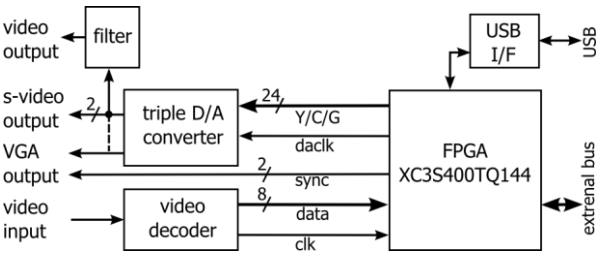

Figure 7. Hardware components of the video processing development system [12]

We designed several IP components in VHDL for video processing applications:

- a PAL video decoder (grabber),
- a PAL video generator and modulator and
- a digital generator of computer VGA signal.

B. *Debug Interface Component*

Emulated circuit parameters can be set and observed through virtual RS232 port. An IP debug component was designed to simplify and reuse debugging structures. The component includes serial interface and a protocol state machine for decoding serial commands.

The component is used for setting values on 1-8 output registers. Each register can be 4, 8, 12, 16, 20, 24, 28 or 32 bits long. Decoding from ASCII hexadecimal input to binary format is performed. The register values can be sampled, converted to hexadecimal numbers and read back to PC.

IV. CASE STUDY

As a case study we describe design and implementation of a video security embedded system. The system is used to observe a window in the PAL video frames and issue alarm condition when the average change of luminance exceeds a threshold.

Figure 8 presents components of the designed video processing system. A PAL video grabber component is used for decoding the digitized video stream. Luminance component is send to a window and graphics engine used for average computation and drawing the frame. Finally PAL video generator components: synchronization and carrier block, modulator and output formatting block are used to produce output video with marked window. We could use an ASIC for the video modulator, but since the FPGA device has enough resources, the embedded system cost is reduced by implementing the modulator in FPGA.

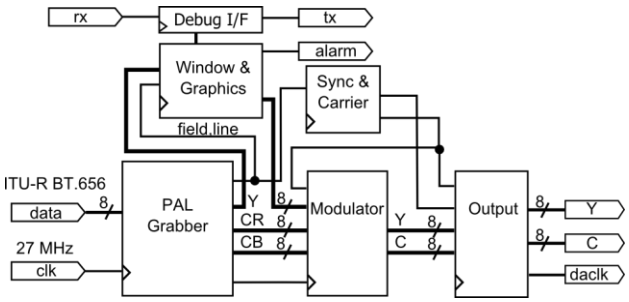

Figure 8: A video processing embedded system for security applications

A. PAL Video Grabber

Video grabber receives input video stream in *ITU-R BT656* format from video decoder. The data stream contains synchronization data and pixel data and the task of video grabber is separation of data and control information. Table 2 shows typical BT656 video data stream values:

TABLE II. TYPICAL ITU-R BT656 VIDEO DATA VALUES

Digitized Video Data	Value
Synchronization sequence	**FF 00 00 status**
Blank sequence	**08** or **01**
Active video Y	**10 - EB**
Active video C_B	**10 - F0**
Active video C_R	**10 - F0**

Synchronization part starts with unique identification sequence FF, 00 and 00 followed by status word. Status word defines even or odd field and state of horizontal and vertical blanking. The status word combination is used in finite state machine to determine start and end of active video lines. The video pixel data arrives in a sequence C_B Y C_R Y. The luminance values (Y) have twice the resolution of the chrominance and an interpolator is used to oversample the values for the linear output stream.

The synthesized PAL video grabber circuit utilized 147 LUT and 95 D flip-flops in a device from Xilinx Spartan-3 technology.

B. Window Processing and Graphics Engine

A window processing block is the core of the embedded security system. Only the luminance values of the video stream and one video field is observed since the sudden change in luminance is enough to trigger alarm condition.

An averaging local filter is applied to produce a dataflow in QCIF resolution in order to save buffer space in the FPGA device. A filter kernel is a 4 x 2 averaging matrix:

$$\frac{1}{8}\begin{bmatrix}1 & 1 & 1 & 1\\ 1 & 1 & 1 & 1\end{bmatrix} \quad (1)$$

The image resolution after filtering is 176 x 144 gray pixels and one window of 64 x 64 pixels is saved in a block RAM buffer. When new pixels are saved, the previous frame values are compared to new values and a sum of absolute difference (SAD) is calculated.

The SAD values of several frames are compared and if they exceed the threshold value an alarm condition is set. The window position and threshold values are defined in registers connected to a debug interface component. These values can be easily changed and observed during hardware verification of the design.

The synthesized circuit requires 3 RAM block components, one for line FIFO in the filter and two for the window buffer.

C. Synchronization Block

The synchronization block receives decoded field and line synchronization bits from video decoder or from the timing generator if decoder is not used in application.

The PAL video data stream consists of 625 lines, divided into 575 active (displayed) video lines and the lines that are part of the blanking interval used for synchronization. Each video line contains horizontal synchronization with a 4,7 μs pulse. At the end of image field is vertical synchronization sequence with five short pulses, five long pulses and finally five short pulses. A short pulse width is 2,35 μs and long pulse with is 27,3 μs. This sequence is repeated twice in a frame and is slightly different for odd and even fields in order to recognize start of the corresponding field with odd and even image lines.

The pulses are generated with a finite state machine and counters. The synchronization block resource utilization is 197 LUT and 64 D flip-flops in the Spartan-3 FPGA technology.

D. PAL Video Modulator and Output Block

The video pixel components are transformed to a composite signal in the modulator. Two orthogonal carrier signals are used for transformation of color differences C_R and C_B to a chrominance signal. The chrominance signal contains information in phase and amplitude, as shown in Figure 9. The PAL video system alternates the carrier phase after each consecutive line in order to minimize impact of phase errors during analog signal transmission.

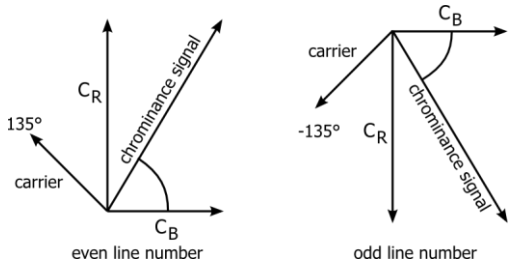

Figure 9: Vector diagram of the modulated signals

Chrominance modulation can be expressed by the equation:

$$C = C_B \cdot \sin(\omega t) \pm C_R \cdot \cos(\omega t)$$
$$\omega = 2\pi f_{SC} \qquad (2)$$

The main part of the modulator is a synthesizer of the carrier signal with exact frequency f_{SC} = 4433618.75 Hz. We could use one synthesized carrier with phase delay, but in order to optimize circuit delays, we produce separate orthogonal carriers. The input clock is 27 MHz and direct digital frequency synthesis method with a phase counter and sine table is used. The table contains 256 data values for one quarter of sinus period and 1024 points are defined for the complete period. Input to the table is current phase and is changed in the defined timing intervals. The circuit contains an accumulator constantly adding a value calculated by the equation:

$$x = 1024 \cdot \frac{f_{SC}}{f_{clk}} \qquad (3)$$

The frequencies ratio is 168.149... Rounding this number to integer could introduce excessive phase error. We multiplied the ratio by 2^{22} and used 32 bit accumulator constantly adding a value 705268427. There is still a minor phase error, but it has no impact to the modulated signal. The two most significant bits of the accumulator output define sine quadrant and next 8 bits are used as inputs to the table. Two tables are used for producing orthogonal sin() and cos() carriers for modulation, as presented in Figure 10.

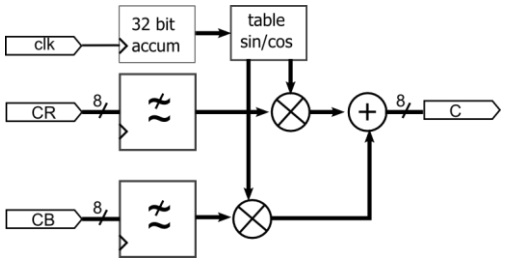

Figure 10: Circuit for color component modulation

Low pass filters are used to limit the badwith of the color difference signals. We used Gaussian 9 tap symmetrical filter with the following coefficients:

$$a_0 = 0.3153 \quad a_1 = 0.2308 \quad a_2 = 0.0903 \quad a_3 = 0.0191$$
$$a_4 = 0.0021 \qquad (4)$$

The bandwidth of the filter is 1,07 MHz, -3dB attenuation is at 1,3 MHz and -20dB at 4MHz. We used Matlab filterbuilder for the filter design.

The modulator should also generate color burst carrier, which is a reference signal for PAL video demodulation. The reference signal is transmitted 5,6 μs after horizontal synchronization pulse. Duration of the reference carrier is around 10 periods. The carrier changes phase ($\pm 135^\circ$) after each line and is calculated by sum or difference of carrier frequency and an amplitude correction:

$$\sin(\omega t) \pm \cos(\omega t) = \sqrt{2} \cdot \sin(\omega t \pm 45^\circ) \qquad (5)$$

We can avoid some multipliers if the sine table values are carefully prepared.

The output module has multiplexer for summation of all generated data and synchronization signals into final composite PAL video, as presented in Figure 11. Optionally the module produces s-video with separate luminance and color component.

The modulator is the largest block in the PAL generator at its utilization is 1619 LUT and 1398 D flip-flops in the Spartan-3 FPGA technology

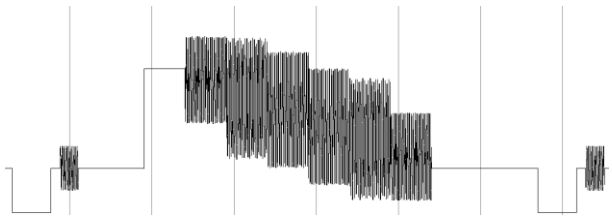

Figure 11: One line of the generated composite PAL signal

The generated PAL signal in Figure 11 is an image from the circuit simulation. Actual analog output is produced by external D/A converter and a reconstruction filter should be used to limit the bandwidth.

V. CONCLUSION

In this paper we presented the test structures and the VHDL components for development of the video processing circuits in programmable devices. The video processing development system used for research and educational implementation of embedded video applications is described.

We analyzed the structure of a typical embedded video processing circuit and designed test benches for efficient verification. With the presented verification methodology we are able to accelerate the simulation by a factor of over 200. The simulation results can be visualized and observed as magnified images in a web browser. The benefit of our approach is that it can be used with the standard programmable design tools and low cost platforms, since we do not require special software or hardware emulators.

Our future work will focus on extending the hardware debugging interface with logic analysis components specifically tailored for the video processing applications.

Abstract - The nonlinear transmission line is a structure where short–duration pulses called electrical solitons can be created and propagated. In this paper, a method to study soliton–like pulses propagation along the nonlinear RLC transmission lines periodically loaded with voltage dependent capacitances is presented. Based on Kirchhoff's law taken in the continuum limit, exact soliton solutions of voltage equation are obtained by symbolic computation using an improved tanh–function method. It is shown that the shape of soliton can be controlled well by adjusting the parameters of the line. These solutions may have important applications in communication systems where solitons are used to codify data.

I. INTRODUCTION

Solitons, self–localized waves, are a special class of pulse–shaped waves that propagate without changing their shape in nonlinear dispersive media. A balancing mechanism between nonlinearity and dispersion is responsible for the appearance of solitary wave or pulse which propagates infinitely [1]. The first–reported soliton was a mono–pulse water wave in a narrow canal where the shallow water possessed both nonlinearity and dispersion. The propagation of modulated waves, such as bright or dark solitons, has been the subject of considerable interest for many years. The optical fiber is yet another example of a nonlinear dispersive medium where optical solitons are observed.

In electronics, nonlinear transmission lines (NLTLs) serve as nonlinear dispersive media where electrical solitons can propagate in the form of voltage waves [2]. A NLTL is a ladder network of repeating inductors and capacitors, where the inductors, the capacitors, or both are nonlinear in their response to current and voltage, respectively. The semiconductor devices such as Schottky diodes and heterostructure barrier varactors can also be incorporated into a soliton generating NLTL. These devices are used to generate oscillations with frequencies up to the terahertz range and pulses with subpicosecond durations [3]. Recently, it has been pointed out that a spatially modulated nonlinear dielectric line can be used to generate solitons at high powers and microwave frequencies. In this type of line, the dispersion comes from the periodicity of the line, while the nonlinearity comes from the dielectric material [4].

These lines are of interest because of their applications in several fields. For example, in the linear regime, the NLTLs can be used as phase shifters in phased antenna arrays [5], where time delay can be controlled by means of a DC bias applied to Schottky diodes acting as variable reactance. Under large signal conditions, NLTLs can serve as impulse compressors or frequency multipliers [6]. Recently, these lines have proven to be of great practical use in extremely wideband (frequencies from DC to 100 GHz) focusing and shaping of signals [7], which is usually a hard problem. Very recently, attempts have been made to study analytically and numerically nonlinear excitations using NLTLs, and it has been shown experimentally that solitons can exist in such systems [8].

The main aim of this paper is to present a method to computational study of solitary waves in nonlinear RLC transmission lines. A circuit model of a NLTL with N identical cells is given in Fig. 1. The series inductance is due to magnetic field effects, and the capacitance is due to electric field coupling between the lines. The losses in the transmission media are depicted by the series and the shunt resistors. These resistors represent the finite conductivity of the conductors and the dielectric insulator between the conductors, respectively. The resistors R_1 and R_2, accounting for the transmission line losses, the linear inductance L, and the voltage–dependent capacitance $C(V_n)$ are the circuit parameters. The resulting circuit is referred to as a distributed model of a nonlinear RLC transmission lines. A distributed model of the NLTL has been proposed to deal with wide–bandwidth signals.

Interestingly, in constructing proposed lossy nonlinear network, we were motivated with a very interesting example of nanobioelectronics problem. Namely, our group was recently modeled ionic currents along microtubules in the eukaryotic cells [9]. We analytically analyzed the possible use of microtubules as protein structure for building biomolecular nanoscale NLTLs in the context of the polyelectrolyte character of these cytoskeletal filaments [10].

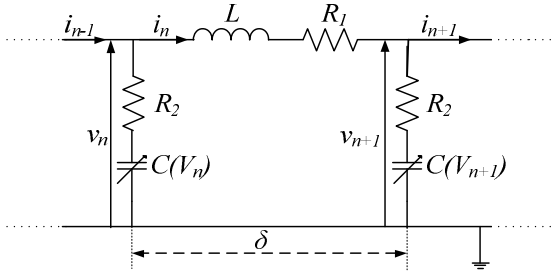

Figure 1. Schematic representation of one cell of the nonlinear transmission line.

The structure of the rest of paper is the following. In Section 2, we present the characteristic of the NLTL under consideration and we write down the voltage equations governing small–amplitude pulses in the transmission line shown in Fig. 1. We undertake the study of the propagation of solitons on the line in Section 3. By applying the symbolic computation using improved tanh–function method, we obtain exact analytical soliton–like solutions of the NLTL. Simulation results for verification of the obtained solution are given in Section 4. Section 5 summarizes results of this paper.

II. Model Description and Voltage Equation

We now consider a NLTL constructed by N elementary cells, where each cell, such as the nth one, contains a linear inductance L in the series branch, a nonlinear capacitor $C(V_b+V_n)$ in the shunt branch with V_n being the voltage across it and V_b a constant DC bias voltage, and the linear resistances R_1 and R_2, see Fig. 1. The reverse–biased diode or MOS varactor can serve as the nonlinear capacitor, and its differential capacitance is $C(V_b+V_n) = dq_n/dV_n$, where q_n denotes the stored charge in the nth capacitor, and it depends nonlinearly on the voltage V_n. For low voltages around the DC bias voltage V_b, the nonlinear capacitance can be approximated by [11]

$$C(V_b+V_n)=\frac{dq_n}{dV_n}=C_0\left(1+2\alpha V_n+3\beta V_n^2+...\right), \quad (1)$$

where C_0 is the linear capacitance of the capacitor, and α and β designate the nonlinear coefficients of the capacitor.

Equation (1) can be the second order curve fitting for the diode characteristics or the varactor characteristics according to the sign of nonlinear coefficients α and β. For the diode the sign of coefficient α is negative and the sign of coefficient β is positive and vice versa for the MOS varactor. In this study, we only consider the case when the perturbation voltage is small in comparison with the equilibrium voltage V_b, therefore, we neglect higher–order terms in (1), keeping only the first two terms of the expansion.

By applying the Kirchhoff current law at node n whose voltage with respect to the ground is v_n, and applying the Kirchhoff voltage law across the two inductors connected to this node, we obtain:

$$i_{n-1}-i_n=\frac{dq_n}{dt}, \quad (2)$$

$$v_n-v_{n+1}=L\frac{di_n}{dt}+R_1 i_n. \quad (3)$$

Similarly, if the voltage across the capacitor is V_b+V_n, where V_b is the bias voltage of the capacitor, we have:

$$v_n=R_2(i_{n-1}-i_n)+V_b+V_n. \quad (4)$$

From (3) we have:

$$\begin{aligned} L\frac{di_{n-1}}{dt}&=v_{n-1}-v_n-R_1 i_{n-1},\\ L\frac{di_n}{dt}&=v_n-v_{n+1}-R_1 i_n. \end{aligned} \quad (5)$$

From (2) we have

$$L\frac{d^2q_n}{dt^2}=L\frac{di_{n-1}}{dt}-L\frac{di_n}{dt}, \quad (6)$$

and including (5) in (6), we get:

$$L\frac{d^2q_n}{dt^2}=v_{n-1}-2v_n+v_{n+1}+R_1(i_n-i_{n-1}). \quad (7)$$

Replacing the expressions for the voltages v_{n-1}, v_n and v_{n+1} from (4) to (7), we obtain that voltages of the adjacent nodes on this lossy NLTL are related via partial differential equation (PDE) as follows

$$\begin{aligned} &L\frac{d^2}{dt^2}\left[C_0\left(V_n+\alpha V_n^2\right)\right]+R_1C_0\frac{d}{dt}\left(V_n+\alpha V_n^2\right)-\\ &-R_2C_0\left\{\frac{d}{dt}\left(V_{n-1}+\alpha V_{n-1}^2\right)-2\frac{d}{dt}\left(V_n+\alpha V_n^2\right)\right.\\ &\left.+\frac{d}{dt}\left(V_{n+1}+\alpha V_{n+1}^2\right)\right\}=V_{n-1}-2V_n+V_{n+1}. \end{aligned} \quad (8)$$

The right–hand side of (8) can be approximated with partial derivatives with respect to distance x, from the beginning of the line, assuming that the spacing between two adjacent sections is δ (i.e., $x_n = n\delta$). Let voltag $V(x, t)$ be a continuous function of the variables x and t so that $V(n, t) = V_n(t)$ and $V_{n\pm1}(t) = V(x\pm\delta, t)$. An approximate continuous PDE can be obtained by using the Taylor expansions

$$V_{n\pm1}=V(x\pm\delta,t)=V\pm\delta\frac{\partial V}{\partial x}+\frac{\delta^2}{2!}\frac{\partial^2V}{\partial x^2}\pm\frac{\delta^3}{3!}\frac{\partial^3V}{\partial x^3}+.., \quad (9)$$

to evaluate the right–hand side of (8), i.e.,

$$V_{n-1}-2V_n+V_{n+1}=\delta^2\frac{\partial^2V}{\partial x^2}+\frac{\delta^4}{12}\frac{\partial^4V}{\partial x^4}. \quad (10)$$

By eliminating terms of higher order than δ^4 as negligible small and considering that the time variations of local voltage V are small compared to the constant background voltage V_b, we could safely assume that time derivative is of the order of small parameter ε as well as the nonlinear voltage terms αV^2 are of the order of ε^2. Thus, we obtain the following nonlinear PDE for the perturbed voltage V:

$$R_2 C_0 \delta^2 \frac{\partial}{\partial t}\left(\frac{\partial^2 V}{\partial x^2}\right) + \delta^2 \frac{\partial^2 V}{\partial x^2} - LC_0 \frac{\partial^2 V}{\partial t^2} + 2\alpha R_1 C_0 V \frac{\partial V}{\partial t} - R_1 C_0 \frac{\partial V}{\partial t} = 0. \quad (11)$$

III. SOLITON–LIKE PULSES IN NLTL

In this study, the improved tanh–function method (ITM) is applied in order to find the analytical solution of the NLTL [12]. The first step in this method is to introduce the voltage in the form of the travelling wave

$$V(x,t) = V(\xi); \quad \xi = x - \mathrm{v}_0 t, \quad (12)$$

where v_0 is undetermined parameter that represents the velocity of propagation. A propagating mode solution of (11) can be obtained by substituting (12) into the PDE (11). Then voltage equation (11) becomes the ordinary differential equation (ODE) of the third order

$$\frac{R_2}{R_1}\delta^2 \mathrm{v}_0 \frac{d^3 V}{d\xi^3} + \frac{L}{R_1}\left(\mathrm{v}_0^2 - \delta^2 \omega_\mathrm{c}^2\right)\frac{d^2 V}{d\xi^2} + 2\alpha \mathrm{v}_0 V \frac{dV}{d\xi} - \mathrm{v}_0 \frac{dV}{d\xi} = 0. \quad (13)$$

Here the parameter ω_c, meaning the cutoff angular frequency, is defined by $\omega_\mathrm{c} = (LC_0)^{-1/2}$ and the maximum velocity of the propagation of waves is $\mathrm{v}_{0\max} = \delta\omega_\mathrm{c}$. After first integration of ODE (13), we obtain

$$A\frac{d^2 V}{d\xi^2} + B\frac{dV}{d\xi} - \mathrm{v}_0 V + DV^2 = \mathrm{c}_1, \quad (14)$$

where c_1 is an arbitrary constant, whose value depends on the initial conditions. Requiring that all functions $V(\xi)$, $dV(\xi)/d\xi$ and $dV^2(\xi)/d\xi^2$ tend to zero as $\xi \to \infty$, the integration constant c_1 is set to be zero. The parameters of ODE (14) read as follows:

$$A = \frac{R_2}{R_1}\delta^2 \mathrm{v}_0, \quad B = \frac{L}{R_1}\left(\mathrm{v}_0^2 - \delta^2 \omega_\mathrm{c}^2\right), \quad D = 2\alpha \mathrm{v}_0. \quad (15)$$

It is observed form (13) that the sign of the dispersion coefficient, A, is always positive, but the sign of the nonlinearity coefficient, D, depends on the nonlinear characteristics of the capacitance. Therefore, the sign of the product AD can be positive or negative, which leads to appearance of dark soliton ($AD < 0$) or bright soliton ($AD > 0$). The parameter B is always positive and involves the effect of dissipation.

We now introduce the new independent variable $Y = \tanh\xi$ and $W(Y) = V(\xi)$ [13], as a polynomial series, due to which ODE (14) transforms to the shape

$$A\left(1-Y^2\right)^2 \frac{d^2 W}{dY^2} + \left\{B\left(1-Y^2\right) - 2AY\left(1-Y^2\right)\right\}\frac{dW}{dY} - \mathrm{v}_0 W + DW^2 = 0. \quad (16)$$

We compare the derivative term of highest–order with the highest order nonlinear term. So, balancing the order of W'' with the order of W^2 in (16), we obtain $m + 2 = 2m \to m = 2$. So the solution takes the form

$$W(Y) = \sum_{i=0}^{m=2} a_i Y^i = a_0 + a_1 Y + a_2 Y^2, \quad (17)$$

where parameters a_0, a_1, and a_2 are to be determined. Inserting (17) into (16), we get a system of algebraic equations:

$$\begin{aligned}
Y^0: &\quad 2a_2 A + a_1 B + a_0^2 D - \mathrm{v}_0 a_0 = 0,\\
Y^1: &\quad -2a_1 A + 2a_2 B + 2a_0 a_1 D - \mathrm{v}_0 a_1 = 0,\\
Y^2: &\quad -8a_2 A - a_1 B + a_1^2 D + 2a_0 a_2 D - \mathrm{v}_0 a_2 = 0,\\
Y^3: &\quad 2a_1 A - 2a_2 B + 2a_1 a_2 D = 0,\\
Y^4: &\quad 6a_2 A + a_2^2 D = 0.
\end{aligned} \quad (18)$$

Solving the above system of algebraic equations with the aid of MATLAB, we obtain the following calculated values of the parameters:

$$a_0 = \frac{1}{D}\left(6A + \frac{1}{2}\mathrm{v}_0\right); \quad a_1 = \frac{6}{5}\frac{B}{D}; \quad a_2 = -6\frac{A}{D}. \quad (19)$$

together with a relation between coefficients B and A as $B^2 = 100A^2$. Finally, using the determined parameters, the exact soliton solution of the voltage equation (11) reads explicitly

$$V(x,t) = \frac{1}{D}\left(6A + \frac{1}{2}\mathrm{v}_0\right) + \frac{6}{5}\frac{B}{D}\tanh\left(x - \mathrm{v}_0 t\right) - 6\frac{A}{D}\tanh^2\left(x - \mathrm{v}_0 t\right). \quad (20)$$

It represents a particular combination of a bell–shaped solitary wave, third term of (20), with a kink–like shock–wave, second term. Here, the solitary wave velocity v_0 is given by the following implicit expression

$$\mathrm{v}_0^2 = 4\left(24A^2 + \frac{6}{5}B^2\right). \quad (21)$$

IV. NUMERICAL SIMULATION AND RESULTS

In order to verify our analytical prediction based on (20), we have also analyzed the NLTL using well–known methods of circuit analysis. To this end, the circuit in Fig. 1 is connected to a source with 50 Ω resistance and a load

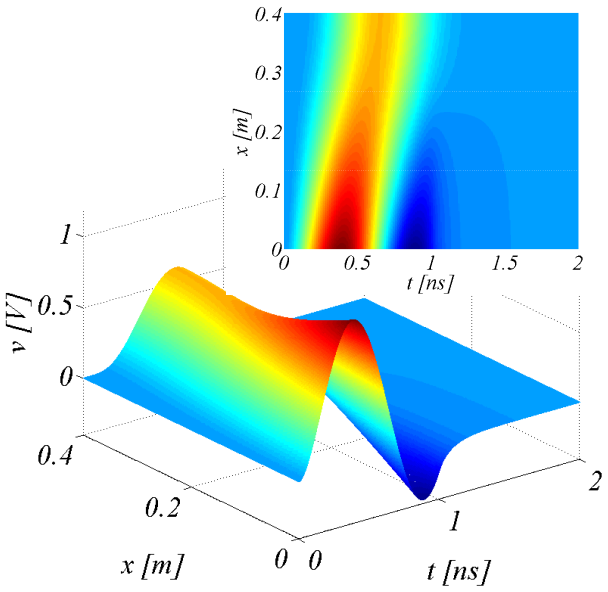

Figure 2. The 3-D plot of bright soliton at different positions, x, obtained from simulation of the NLTL.

with 50 Ω resistance. The number of cells between the source and the load are assumed to be 40. The NLTL is then analyzed using a standard time–domain technique for nonlinear circuits [14]. The method uses finite–difference applied to the differential equations governing the voltages and current of the circuit.

In the simulation, we first consider the NLTL with a varactor, the linear inductance L = 2.5 nH, and the linear resistances R_1 = 0.1 Ω, and R_2 = 1 Ω. The varactor's parameters are linear capacitance C_0 = 1 pF, and nonlinearity factor α = 0.2 V^{-1}. Because of the positive sign of the product AD, as predicted by the analytical solution, a bright soliton will be formed along the transmission line. The NLTL is excited by the input voltage given by [11]:

$$V_{in}(t) = V_m \operatorname{sech}\left(\frac{t-\tau_0}{T_0}\right)\cos(2\pi f t), \qquad (22)$$

where the amplitude V_m = 1 V, the parameters τ_0 = 0.3 ns, and T_0 = 1 ns. The carrier wave frequency is chosen to be f = 2.5 GHz in passband of the transmission line, below ω_c.

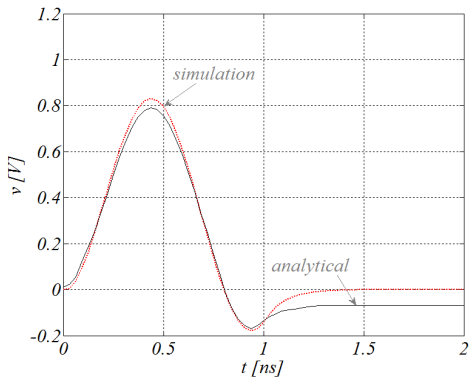

Figure 3. Comparison between the waveform envelopes obtained from the analytical solution and the simulation at x = 0.1 m.

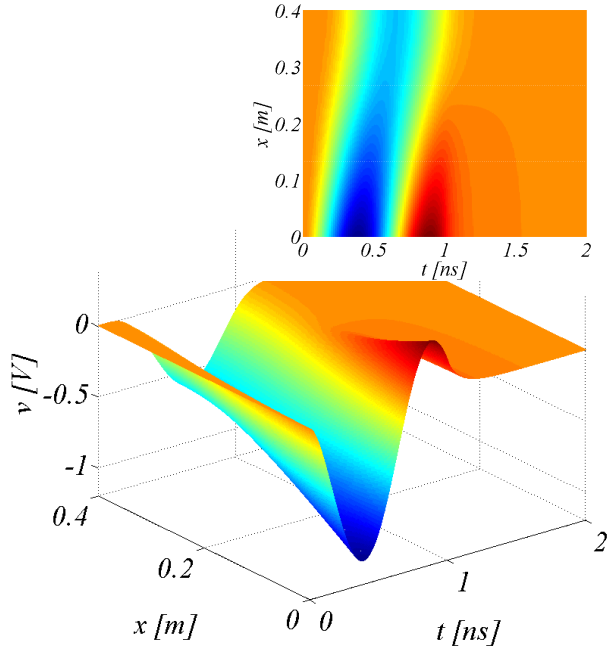

Figure 4. The 3-D plot of dark soliton at different positions, x, obtained from simulation of the NLTL.

Propagation of this pulse along the transmission line is simulated and the obtained envelope waveform at different positions, x, is depicted in Fig. 2. As seen in this figure, the soliton–like pulse preserves its shape along the propagation path. According to the analytical calculations, this circuit because of its positive nonlinearity cannot support dark solutions. As observed in Fig. 3, it presents a good agreement between the analytical and simulated results at x = 0.1 m.

Now, we consider the NLTL with a reverse–biased diode and the same values for the inductance and resistances. The diode's parameters are linear capacitance C_0 = 1 pF, and nonlinearity factor α = – 0.25 V^{-1}. In this case, the sign of the product AD is negative. Therefore, if this circuit is excited by a dark initial signal, a dark soliton will be generated. The envelope waveform obtained from the finite–difference method at different positions, x, is depicted in Fig. 4. As observed in Fig. 5, we get a good agreement between the analytical and simulated results. According to the analytical calculations, this circuit because of its negative nonlinearity cannot support bright solutions.

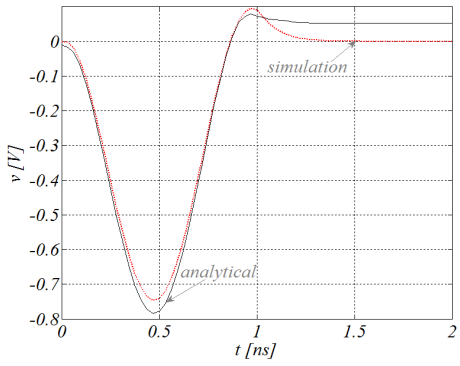

Figure 5. Comparison between the waveform envelopes obtained from the analytical solution and the simulation at x = 0.15 m.

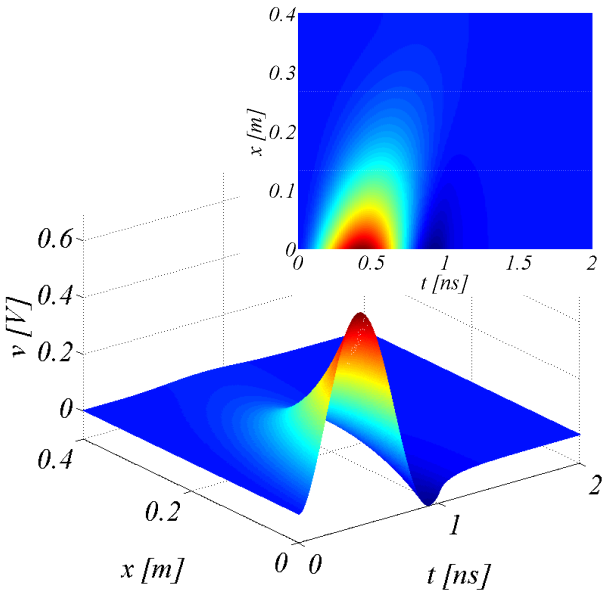

Figure 6. The influnce of dissipation on waveform of the envelope soliton.

Finally, let us consider the propagation of soliton–like waves in the case of larger values of resistance than in the first two cases. In this case, we consider the NLTL with a varactor, inductance, and linear resistances $R_1 = 10\ \Omega$, and $R_2 = 5\ \Omega$. The varactor's parameters and linear inductance are the same as observed in the first case. In Fig. 6 is shown the influence of dissipation along the line for the envelope soliton. We can conclude that dissipation acts on the amplitude of the soliton but not on its profile. The amplitude of soliton–like pulsess decreases with the increase of the resistances line. Thus, our results suggest that the losses must be reduced in order to improve the propagation of solitons.

V. CONLUSION

In this paper, we analytical and numerical studied the propagation of soliton–like signals in a nonlinear RLC transmission line. Using Kirchhoff's laws has been shown that the voltages along the line are governed by a third–order nonlinear PDE. The coefficients of the obtained voltage equation show that the dispersion coefficient, A, is always positive, but the sign of the nonlinearity coefficient, D, is determined by the characteristics of the varactor or the reversed biased diode. Depending on the sign of the product AD, the proposed NLTL can generate either bright or dark solitons. Also, we found the soliton solution of circuit equation using ITF method. From the analytical solution is possible to choose the suitable parameters of NLTLs to satisfy the required application or to compare the analytical results with the experimental results. We have verified generation of bright and dark solitons using a circuit simulator based on a finite–difference method. A good agreement is observed between the analytical prediction and the simulation results. Our results suggest that the losses must be reduced in order to improve the propagation of soliton–like pulses, because the amplitude of soliton decreases with the increase of the resistances line.

***Abstract*— In this paper we present an ink-jet printed coplanar waveguide (CPW) inductors in flexible technology. We show design, fabrication, characterization and measurement technique of such devices. This is solution for ultra low-cost mass production. CPW inductors were developed as a technology for much simpler and faster fabrication on/in plastic foil. Structures are printed on Kapton substrate with polyamide silver nanoparticle ink.**

***Keywords*— Flexible technology, inductors, ink-jet printing, printed electronics**

I. INTRODUCTION

Printed flexible technology is one of the best methods for making very precision circuits on flexible printed circuits boards (flexible PCBs). This technology is very usable for fabricating printed electronics, solar cells, mobile phones, Radio Frequency Identification (RFID), Wireless Local Area Networks (WLAN) antennas, smart cards, etc. It represents low-cost green technology, and most of the applications are printed in one layer.

As a demand for low cost, flexible and efficient electronics increases, the materials and integration techniques become more and more critical and face more challenges, especially with the ever growing interest for "cognitive intelligence" and wireless applications, such as RFID, WiFi, WiMax. For an optimal RF performance, substrate material characterization for electronics such as antennas, filters and transmission lines becomes a must, especially for low-cost materials. A fast process, like ink-jet printing, can be used efficiently to print electronics on/in plastic or paper substrates [1, 2].

Printed electronics is gaining wide momentum owing to the many benefits it offers over conventional electronics, such as low fabrication cost, long switching times, and simple fabrication. This technology has found use in a plethora of applications ranging from displays and lighting to RFID, sensors, and batteries. The global printed electronics market is expected to reach $24.25 billion by 2015. Increased miniaturization, technological changes, and portability needs of electronic products in different sectors such as telecommunications, packaging, automotive, and medicine are driving the demand for flexible electronic products in the market [3]. There are significant growth opportunities for printed electronics in end-user markets such as consumer electronics, military, power generation, healthcare, and logistics.

Low-resistance printed conductors are crucial for the development of ultra-low cost electronic systems and components such as high-Q inductors, capacitors, tuned circuits, and interconnects. Because of that, we have designed coplanar waveguide (CPW) inductors without back ground metallization. The goal of this research is to transfer knowledge previously gained on fabrication in non-flexible technologies. We developed meander-type inductors in low temperature co-fired ceramic (LTCC) and different type inductors in ceramic co-processing technology [4, 5], and passive components in flexible technology [6].

The electrical resistance of printed metal lines is dependent on a number of variables: type of nanoparticle, printed thickness, and sintering temperature. Printed thickness depends on: wetting characteristics of the substrate surface, dot size, substrate temperature, and viscosity [7].

In this paper, we present CPW inductors in flexible technology. In Section II is presented design and ink-jet fabrication process of CPW inductors on plastic Kapton foil. In section III are shown measurement results and characterization of presented structures. The reached conclusions of the obtained results follow finally in the Section IV.

II. DESIGN AND INK-JET FABRICATION PROCESS OF CPW INDUCTORS

A. Design of CPW Inductors

Design, modeling and simulation of CPW inductors are obtained using electromagnetic simulator, built in software package Microwave office (MWO, AWR Corp).

Designed CPW inductors are two-port meanders with 1, 1.5 and 3 turns (n number of turns). Line paths in presented structures have width $w = 200$ μm. Around CPW inductors structure is ring-shape ground plane, which is replacement for background metallization. In that manner, structures are manufactured in low-cost one-layer fabrication process.

Designed CPW inductor on flexible substrate is presented in Fig. 1. All geometrical parameters of interest are clearly marked: the width of the conductive line w, the spacing between adjacent segments s, outer dimensions of the inductor

d_x and d_y, and the total thickness of the substrate CPW inductors d. In this case, d is thickness of Kapton substrate.

3D electromagnetic (EM) model of CPW inductor, modeled in MWO, contains an additional top air box that is required for defining the boundaries of the EM enclosure. The top boundary was modeled as "approximately open."

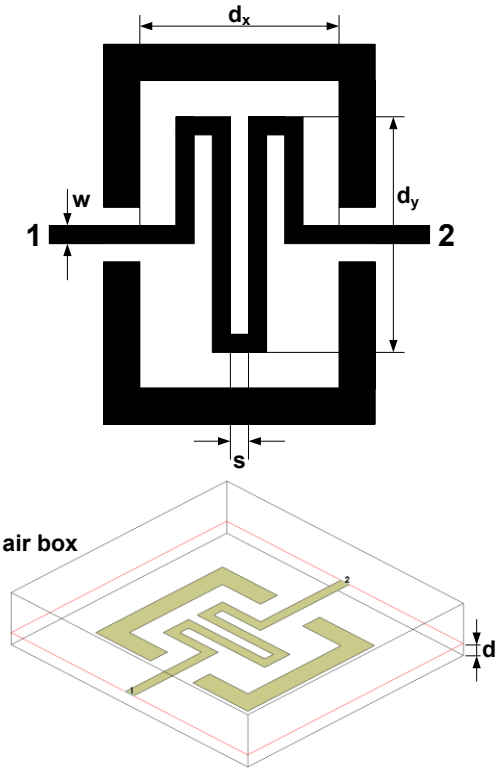

Fig 1. Geometric structure of CPW inductor meander type with 1.5 turn: top view and 3D model (built in MWO).

Geometrical parameters of designed CPW inductors are presented in the Table I. Ring ground is rectangular path with 400 µm line width around meander structures. Depending on the number of turns n, we obtain the projected value of inductance, which is directly related to the final dimensions of the CPW inductors.

TABLE I.
GEOMETRICAL PARAMETERS OF FABRICATED CPW INDUCTORS

	CPW1x200	**CPW1.5x200**	**CPW3x200**
n (turn)	1	1.5	3
dx (mm)	1.8	2.2	3.4
dy (mm)	2	2	2
d (µm)	75	75	75
s (µm)	200	200	200
w (µm)	200	200	200

Parameters of material used for inductors' fabrication influence on their performance. Influence of the most important parameters of the substrate such as dielectric loss (tan δ) and relative permittivity (ε_r) are especially significant. Used plastic foil Kapton has dielectric loss tan δ = 0.0019 and relative permittivity ε_r = 3.2 [8].

B. Fabrication Process: Ink-Jet Printing of CPW Inductors

Printed electronics uses different printing techniques, namely ink-jet, screen, flexography, gravure, offset lithography, nano-imprint lithography, and some proprietary printing techniques developed by market players. Printed electronics technology makes use of conductive and dielectric inks. Plastic, glass, and paper are the commonly used substrates for developing printed components [3].

CPW inductors in flexible technology are printed on plastic/organic Kapton substrate (75 µm thick) with silver nanopatricle ink, using ink-jet printer Dimatix Materials Printer DMP-3000 [9], as shown in Fig. 2. To ensure the ink droplets sufficiently overlap, 25 µm drop spacing was selected. Drop spacing determines the thickness of printed layers. In Fig. 3 are presented ink-jet printed CPW inductors on flexible substrate with real dimensions, and enlarged section.

The ink used here contains silver nanoparticles capped with a polymer coating that keeps the particles in a colloidal suspension. Inks with other metallic nanoparticles such as gold are also available. Once the silver ink has been printed, it can be sintered at a low temperature (100°C-300°C) to form electrically conducting lines, enabling low temperature substrates such as paper [1] and polyimide to be used.

After printing process, structure goes in furnace for sintering process at 200ºC for 40 minutes. The conductivity of the conductive ink varies from 0.4-2.5x10^7 Siemens/m depending on the curing temperature [10]. Expected conductivity of printed silver layers with presented printing and sintering process is below 1x10^7 Siemens/m.

After ink-jet printing, a low temperature sintering step guaranteed a continuous metal conductor, providing a good percolation channel for the conduction electrons to flow.

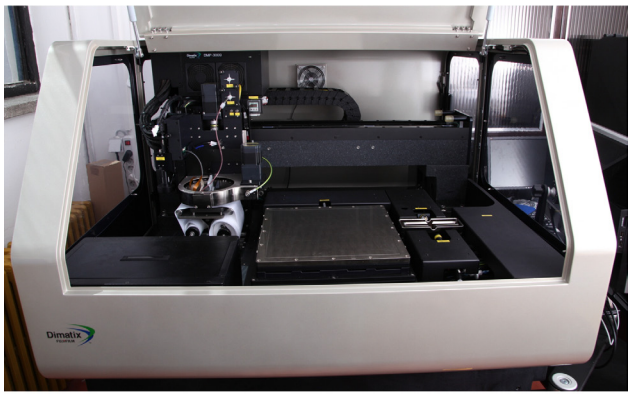

Fig 2. Dimatix Materials Printer DMP 3000 [8].

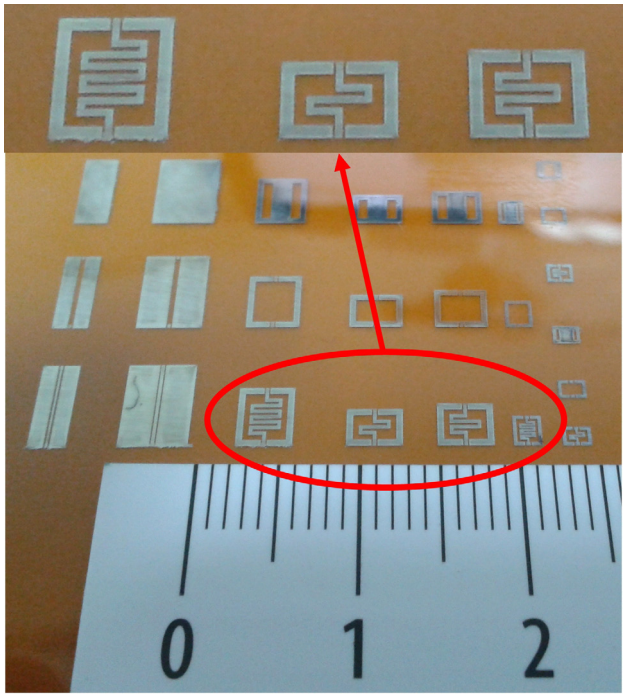

Fig 3. Ink-jet printed CPW Inductors on flexible substrate (in cm).

III. Measurement Results and Characterization of CPW Inductors

Realized structures are measured with Agilent N5230A PNA-L vector network analyzer (VNA), Süss MicroTec RF probe station PM5, and coplanar ground–signal–ground (GSG) Cascade Microtech probes (|Z| *probes*). The measurement system was calibrated using SOLT (Short-Open-Load-Thru) calibration technique using Cascade Microtech's calibration substrate 101-190. Measurement results are obtained in frequency range from 1 GHz to 35 GHz. Measurement set-up and GSG probe pads in one moment of measurement are shown in Fig. 4.

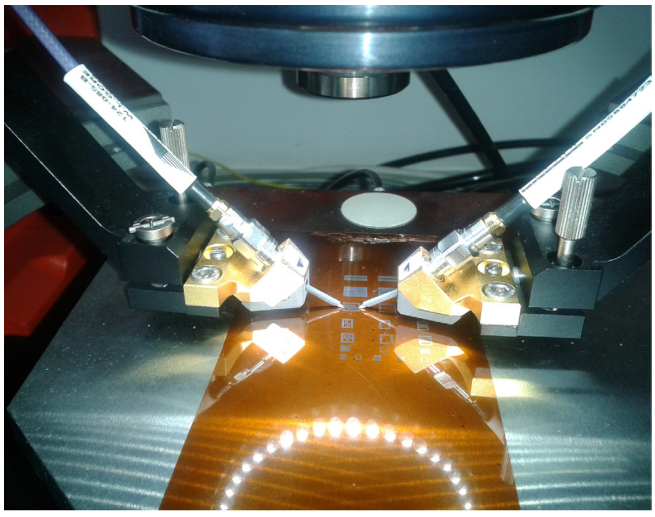

Fig 4. Measurement setup and structure in one moment of measurement.

After calibration of the measurement system, measurement of scattering parameters (S-parameters) of fabricated inductors has been performed.

From S-parameters we extracted basic electrical parameters of inductors, such as inductance, and Q-factor. From S-parameters, through Y and Z matrix we obtained presented results for inductance and Q-factor.

Effective inductance L and effective quality factor in two-port measurement can be calculated by using input impedance through Y matrix parameters as follows

$$L = \frac{\mathrm{Im}\left(\frac{4}{Y_{11}+Y_{22}-Y_{12}-Y_{21}}\right)}{2\pi f}, \tag{1}$$

$$Q = -\frac{\mathrm{Im}\left(Y_{11}+Y_{22}-Y_{12}-Y_{21}\right)}{\mathrm{Re}\left(Y_{11}+Y_{22}-Y_{12}-Y_{21}\right)}. \tag{2}$$

For symmetric inductors, Y_{22} and Y_{21} are approximately equal to Y_{11} and Y_{12}, respectively, so the following approximated equation s can also be utilized as shown in [11]

$$L \cong \frac{\mathrm{Im}\left(\frac{2}{Y_{11}-Y_{12}}\right)}{2\pi f}, \tag{3}$$

$$Q \cong -\frac{\mathrm{Im}\left(Y_{11}-Y_{12}\right)}{\mathrm{Re}\left(Y_{11}-Y_{12}\right)}. \tag{4}$$

Calculated values of effective inductance (at 1 GHz and quality factor maximum frequency f_{Qmax}) and quality factor Q extracted from measured results of all CPW inductors are presented in Table II.

TABLE II.
Extracted Parameters From Measurement Results

	CPW1x200	**CPW1.5x200**	**CPW3x200**
L at 1 GHz (nH)	1.959	2.586	4.457
L at f_{Qmax} (nH)	1.78	2.53	4.52
$Qmax$	3.5	3.167	2.231
f_{Qmax} (GHz)	6.865	6.27	3.656

Measurement results of CPW inductors in flexible technology, such as inductance and Q-factor, are presented in Fig. 5 and Fig. 6. From these measurement results we can see similar behavior with inductors in different technology.

By increasing the number of turns (n) the inductors will have greater inductance (see Fig. 5), which cause the reduction of the self resonant frequency. Because of that, parasitic capacitance became larger. Q-factor of fabricated CPW inductors is in the range of 2-3.5 (see Fig. 6), which is relatively low value compared to different technology, like LTCC. With increasing the number of turns n, the Q-factor reduces, and its maximum moves to lower frequencies.

The maximum value of Q-factor affects conductivity of printed silver-ink. Maximum value of Q-factor could be increased in two different ways. One of these is increasing contents of silver particles in polymer ink enhancing material conductivity, or usage of lower resistive ink. Another way is multiple printing of conductive lines with intent to obtain thicker conductive lines.

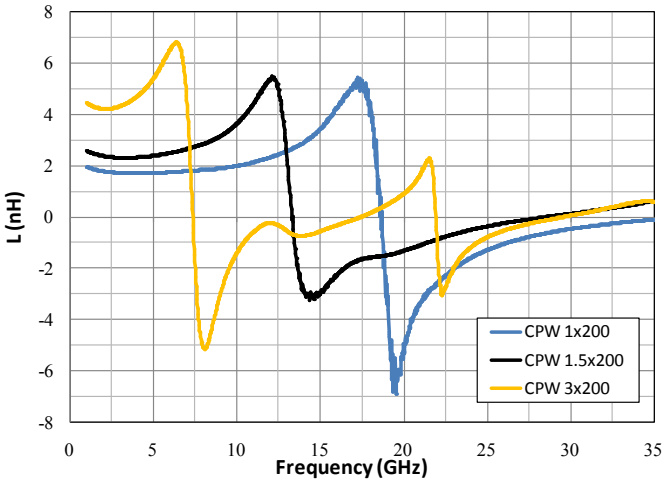

Fig 5. Inductance of meander type CPW inductors.

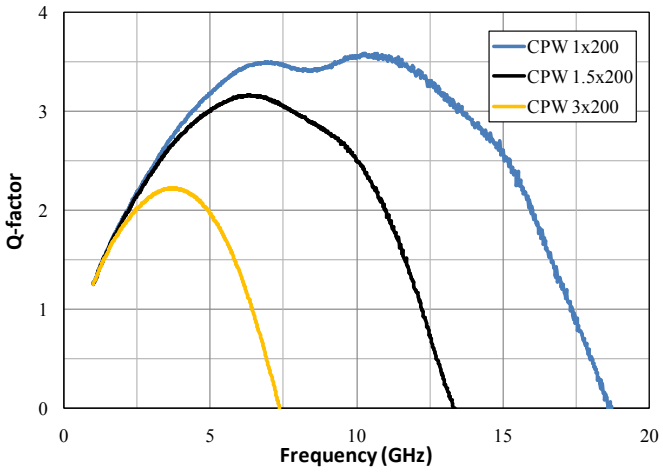

Fig 6. Q-factor of meander type CPW inductors.

IV. Conclusion

Ink-jet printing shows a very promising future for ultra-low-cost fabrication process of passive microwave circuitry and interconnects.

This paper presents the CPW inductors made in flexible PCBs technology. The results of inductor parameters are given, such as inductance and Q-factor. These devices have high operating and self resonant frequencies, up to 17 GHz. Q-factor has somewhat smaller value. If we want to achieve higher Q-factor, reduction of serial resistance of CPW inductors and/or increase the thickness of the layer or increase the concentration of silver containing in polymer silver-ink needs to be performed.

Universal Wireless Communication Detector (UD-100) - Preventing of high-tech cheating methods

J. Bajić*, V. Milosavljević*, V. Rajs*, M. Slankamenac*, M. Živanov*
* University of Novi Sad/Faculty of Technical Sciences/Department of Power, Electronics and Communication Engineering/Novi Sad Serbia
bajic@uns.ac.rs

Abstract: In this paper the implementation of the device for wireless communication detection is presented. The system measures RF electromagnetic field strength for frequencies from 100 MHz up to 2.4 GHz and has wide range of adjustable sensitivity. Implemented device provides detection of cellular phone activities in all three main operating bands, and detection of other types of wireless communication such as radio communications, Bluetooth, Wi-Fi and so on. The device presents an improvement of a previous version of the detector MD-150. Measurement results are displayed on LED bar providing easy user readings and device operating. The system is battery powered, portable and can fit in any pocket.

I. INTRODUCTION

With technology development and miniaturization of devices in telecommunications, problem of citizen privacy became more significant. The problem of mobile phone use on places where their use is forbidden such as exams is also increasing. A device that is mostly used for this purpose is mobile phone with miniature headphones called "bugs" that communicate with the phone via Bluetooth connection. This combination without detector, which is proposed here, represents ideal solution for cheating on exams.

II. METHODS OF HIGH-TECH CHEATING

The problem of cheating by using wireless communications with micro earphones has rapidly increased, as a consequence of price decrease of those systems, their easy use, impossibility to detect them with the naked eye and their great expansion on the market [1]. The price of renting such equipment is about 20-30€ per day, what in fact represents the price of passing an exam. Nowadays, the price of the whole wireless communication system is from 80€ to 300€, so more and more students can afford to buy that system, and later rent it or share with their friends. This caused an expansion of use of such systems for cheating in the school system. First, it started at universities, and lately it expanded into secondary schools. There is a reasonable risk of spreading this phenomenon in primary schools as well. Cheating on the written exams is the easiest (pass rate 90%), while some sellers claim that there is also great pass rate on the oral exams (over 80%). Many professors are under the misapprehension that they will prevent smuggling the test out of the room by forbidding students to take the test with them out of the classroom or leaving the room during the exam. There are many ways of smuggling the test out of the exam room [2]:

- Smuggling the exam questions out of the exam room
- Dictating questions in the miniature microphone
- Taking photo of the test by using mobile phone and sending that photo to a colleague outside the building
- Shooting the exam questions by using a camera of a button size or by using a micro camera in a pen (Fig. 1).

Using the system for cheating is quite easy (Fig. 2):

- It is necessary to connect a receiver (in most cases it is a mobile phone) to an adapter with antenna

Figure 1. A micro camera in a pen

Figure 2. A system for cheating on exams

(which is put under the clothes, most often around the neck).

- There is a wireless communication between the antenna and the invisible micro earphone placed in the ear. Nothing can be noticed from the outside.
- The colleague on the other side of the phone line dictates the answers, and these can be only heard by the colleague with the micro earphone.

III. PROJECT REQUIREMENTS AND HARDWARE IMPLEMENTATION

Mobile phones today operate on three frequencies – 900 MHz, 1800 MHz and 2100 MHz, but it is still possible to detect activities of such devices, despite their small dimensions and relatively low radiation. There are certain requirements that the device for detection of mobile phone activities should satisfy. First of all, such device should be light weight and small in dimensions, in order to fulfill the demand for easy portability. If the device is to be installed in every object individually, it would not be cost-effective to use such device for the intended purpose. Another requirement that must be satisfied is ease of use. Device must be simple to use because it is not only intended for people who work in the field of electronics, but for wide population of people in the field of education. The visual representation of the information about the location of the mobile phone should be provided in the simplest form. In this implementation, the visual representation is given through a number of light emitting diodes or LEDs (three green, three yellow and three red). The diodes flash when the device detects an active mobile phone. The number of flashing LEDs indicates the signal strength, which corresponds to the distance to the active mobile device [3].

The goal of this project was to make a small portable device that can detect transmitted RF waves in wide frequency range. Range from 100 MHz up to 2500 MHz is accepted as adequate because it covers FM range, both GSM and 3G ranges, as well as 433 MHz and 2400 MHz bands, which are used by great number of wireless devices.

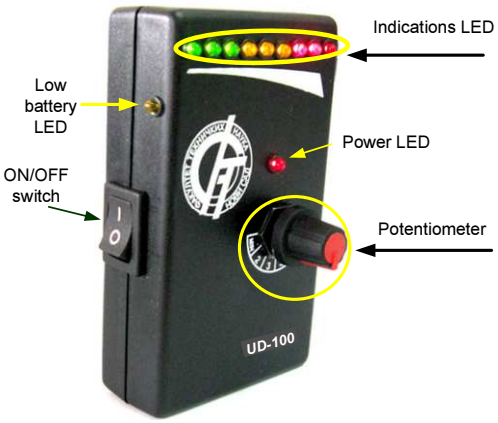

Figure 3. UD-100 universal wireless communication detector

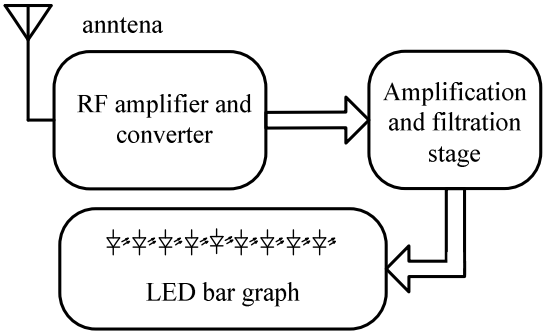

Figure 4. UD-100 Signal processing block structure

Photograph of UD-100 Universal wireless communication detector is displayed on Fig. 3. On front panel aforementioned LED bar is placed, providing to operator clear and fast reading of active transmitter presence. On the right side on/off switch is located [4]. An internal antenna is used because it is more practical during detector use and has shown satisfactory results. During designing phase the problem of detector sensitivity has appeared. If detector sensitivity is too high, it would be hard to localize exact position of transmitter. On the other hand, it was intended for transmitter to have the biggest possible distance range of detection. That problem is overcome by adding one potentiometer for sensitivity regulation. In that way presence of active mobile phone can be detected at longer distances and by reducing sensitivity the exact location of the transmitter can be determined.

Whole device is battery powered via two AAA batteries that are also placed inside casing.

IV. SIGNAL PROCESSING BLOCKS INSIDE DETECTOR

UD-100 can be separated into several functional blocks that are displayed on Fig. 4. The input block consists of receiving antenna, RF amplifier and converter, based on Analog Devices specialized chip that is used in mobile devices for measuring network signal strength as

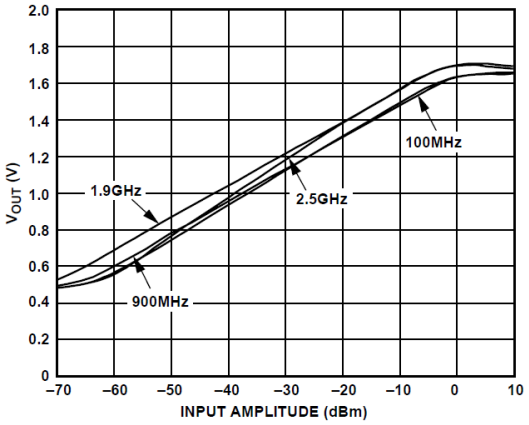

Figure 5. Output of the RF block for different frequencies in dependence of input field strength

well as for control of output power in RF power amplifiers. In Fig. 5 characteristic of the RF block in dependence of the input field strength is given. This block uses a cascade of eight amplifier/limiter cells, each having a nominal gain of 8 dB, which produces a total gain of 64 dB for amplification of the input RF signal [4]. At each amplifier output, a detector (rectifier) cell is used to convert the RF signal to baseband form. Output from this block is DC voltage proportional to strength of RF signal measured in dBm.

In order to increase sensitivity of the detector a half-wave monopole antenna has been implemented. Half-wave antenna is selected based on its simplicity and ease of implementation. In fact it is a single wire 8 cm long so it does not require a lot of place in the housing and has shown satisfactory results.

Since detected RF electromagnetic field has relatively small amplitude, an additional amplification stage had to be implemented. That is done in second block. In addition to amplifiers, a filtration stage is also implemented in this block in order to eliminate high frequency interferences that may occur. Output of this block is a DC signal ranging from 0 to 5V, proportional to the input RF field strength.

As it can be seen from Fig. 5 at output of the RF block there is DC offset voltage of approximately 0.5V. This offset voltage must be eliminated, otherwise we can come to the wrong conclusion about the RF radiation. In Fig. 6 is given circuit that eliminates DC offset voltage (operational amplifier U1) and amplifies signal (operational amplifier U2).

Fully adjusted signal is further taken to section for display of measured data. Since exact numerical data is not necessary and in order to provide fast and easy user readings, LM3914 chip is used to drive LED bar. The LM3914 is a monolithic integrated circuit that senses analog voltage levels and drives 10 LEDs, providing a linear analog display [5]. It is used in a bar graph mode. Current drive to the LEDs is regulated and

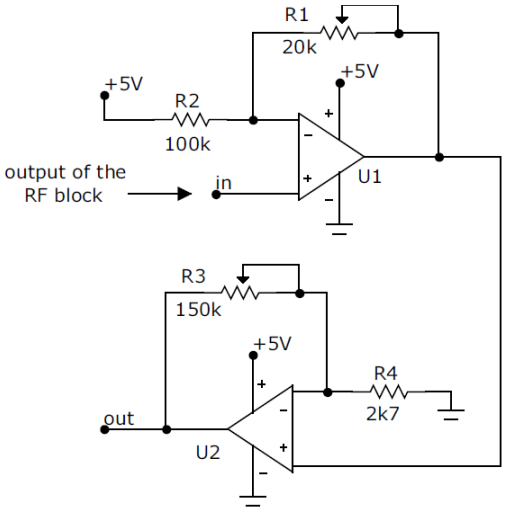

Figure 6. Circuit for elimination of DC offset voltage signal amplification

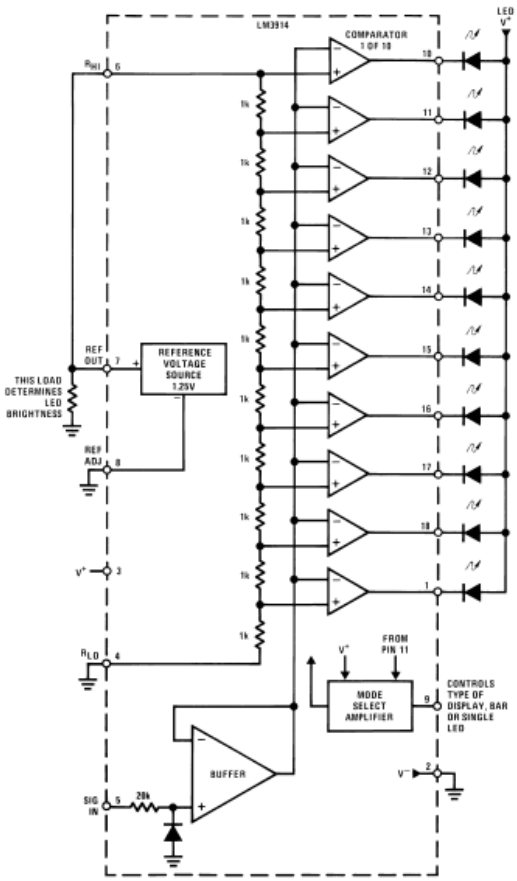

Figure 7. Internal schematic of the LM3914 LED bar graph driver

programmable, eliminating the need for resistors (Fig. 7). The circuit contains its own adjustable reference and accurate 10-step voltage divider. The input buffer drives 10 individual comparators referenced to the precision divider. Depending on input voltage level (field strength), LM3914 activates the appropriate number of LEDs.

V. POWER SUPPLY

Mobile phone detector power supply consists of two main blocks (Fig. 8): DC-DC converter block and LED indicator block. As a power source two AAA 1.5 V batteries are used.

A. DC-DC Converter Block

For this project MAX856 step-up DC-DC converter is used. It is a high-efficiency, CMOS switching regulator for small, low input voltage or battery-powered systems. MAX856 accepts a positive input voltage between 0.8V and 5V and converts it to a higher, pin-selectable output voltage of 3.3V or 5V (5V for this device). The MAX856 combines ultra-low quiescent supply current and high

Figure 8. Power supply block diagram

efficiency to give maximum battery life [6]. An internal MOSFET power transistor permits high switching frequencies. This benefit, combined with internally set peak inductor current limits, permits the use of small, low-cost inductors. The MAX856 series contains an on-chip comparator for low-battery detection. If the voltage at LBI pin falls below internal reference voltage (1.25V) of the regulator, LBO pin (an open drain output) sinks current to GND. The low-battery monitor threshold is set by simple voltage divider. In this implementation the threshold voltage is set to 2.3V.

VI. THE USE OF WIRELESS COMMUNICATION DETECTOR UD – 100

The device is primarily intended for using in the classrooms and amphitheaters in order to detect active mobile phones as the sources of a high-frequency magnetic field. In the following part the use of detector will be described under the assumption that we are in some classroom and that we are looking for an active mobile phone. When we enter the classroom, we put the device on the table and we turn on the switch on the left side. When we see that the red diode is turned on that is the sign that the device is working. On the basis of length of the classroom we adjust the device sensitivity. The device sensitivity is adjusted on the potentiometer. On the scale under the potentiometer there are marks: MIN-2-3-4-5-MAX. Distances that correspond to these marks are respectively 0.5m-1m-5m-10m-15m-30m. These values are not relevant because the radiation of a mobile phone depends on its distance from the base station. More it is distant from the base station, more it radiates.

The question arises: "How do we come exactly to the location of the mobile phone?"

Since all diodes are turned on that is the sign that one of the mobile phones in the classroom is active. Then we lower the detector sensitivity by adjusting the potentiometer to MIN. After that, we take the device in our hand and walk across the classroom. As we approach to an active mobile phone more diodes turn on. When we come to an active mobile phone all diodes will turn on and in this way we know the location of the searched mobile phone.

In the given description the assumption was that the mobile phone was searched for in the classroom, and of course the device can be used in other places for detection of other sources of high-frequency electromagnetic radiation

The answer on the question why it was decided to make a detector, and not a jammer or some similar device is following:

- Using jammer is not legal, because it is forbidden to block public frequencies.
- Jammers of great power have a bad influence on human organism because of their high level of radiation.
- Jammers are not reliable for many kinds of wireless communications which are not permitted (they only block narrow range of frequencies).
- Jammers have big dimensions and their transport is not simple in comparison to detector of this kind.
- Jammers are much more expensive.

VII. CONCLUSION

In spite of UD-100 low price and relatively simple design it represents reliable and flexible system with possibility of further development. High measurement sensitivity enables monitoring of bigger rooms such as amphitheater by using only the one detector UD-100. Device has been tested and shown good results. In city conditions we have detected mobile phone activity on distance of 20 m and with optical visibility up to 45 m which is enough for one conference room or amphitheater.

Investigation of electrically small monofilar spherical helical antenna used for mid-range wireless power transfer

M. Škiljo* and Z. Blažević*

* University of Split/ Faculty of Electrical Engineering, Mechanical Engineering and Naval Architecture, Split, Croatia
msekelja@fesb.hr

Abstract - This study is focused on electrically small monofilar spherical helical antenna for wireless power transfer (WPT) based on resonant coupling. WPT systems with different antenna geometry and loads at the receiving antenna are simulated and compared. The simulation results demonstrate some key WPT concepts including: the frequency splitting, critical coupling, impedance mismatch and the performance of electrically small antennas in WPT system design. By varying the spherical helical antenna geometry (diameter and number of turns) it is possible to achieve an efficient mid-range WPT at different frequencies. The antennas that best utilize the same physical volume achieve better power transfer efficiency over distance.

I. INTRODUCTION

First wireless power transfer (WPT) experiments were carried out by Tesla at the end of 19th century guided by the idea of providing the electricity "without wires" worldwide [1]. WPT system based on microwave radiation using highly directional antennas can deliver power to great distances with high efficiencies [2] but it requires uninterrupted line-of-sight and a sophisticated tracking and alignment equipment for mobile users. Alternatively, if omni-directional antenna is used to maintain mobility, a vast majority of energy is wasted due to decreasing power density with distance.

Today, when electrical wire grid delivers energy almost everywhere, we are faced with a different problem, a continual surge of wireless devices into our homes still tied to a number of charging wires. Recent advancements in WPT technologies for short and mid-range distances are offering a wide variety of applications and potential product implementation in RFID systems, charging consumer electronics and electronic vehicles (EVs) [3]. Inductive magnetic coupling WPT offers high efficiency over short range (tens of centimeters) while resonant magnetic coupling extends this range to mid-range distances (1-2 m) with same-frequency resonant devices interacting weakly with off-resonant objects in the surrounding environment.

Since Soljacic and his group demonstrated an efficient mid-range wireless power transfer using two resonant loop antennas in 2007 [4], there has been much interest among electromagnetic community for practical applications of the resonant magnetic coupling phenomenon [4 - 11]. The feasibility of WPT depends on power transfer efficiency estimated usually by a numerical or analytical method. A spherical mode theory is used to solve the electromagnetic interaction between two antennas in resonant coupling because antennas used for WPT are electrically small and generate predominantly the lowest order spherical modes [5]. Numerical approach can provide a good assessment of WPT key parameters [6] and demonstrate that some theoretical PTE boundaries can be realized [7]. Also, it is shown that a simple method based on equivalent circuit model and measurements of coupling coefficients can be useful tool for WPT system design without complex electromagnetic analysis [8].

Electrically small antennas can be represented as a lumped RLC circuit [12] thus making the calculation of antenna parameters and coupling coefficients simple and straightforward. It is shown that small antennas need to have high radiation efficiency in order to maximize the power transfer beyond the coupled mode region [5]. In order to improve the radiation efficiency folding concept can be used. Folded spherical and cylindrical helical antennas achieve very high radiation efficiency and low Q factor [7, 13].

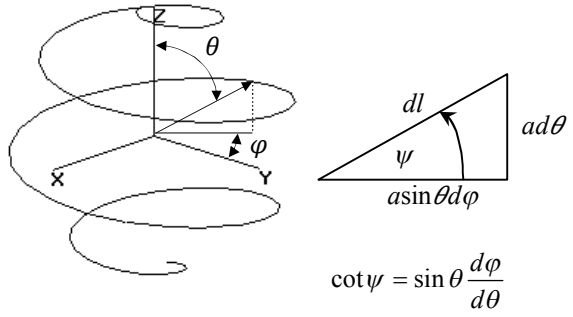
In this paper, we will focus on monofilar spherical helical antenna design for resonant coupling based WPT. Section II presents the circuit models of electrically small antennas and a WPT system where some design issues are discussed. In section III numerical code is used to investigate the WPT system with spherical helical antennas and obtain the simulation results for power transfer efficiency (PTE) in the case of different antenna geometries and loads. The discussion of the results is given in Conclusion.

II. SIMPLIFIED EQUIVALENT LUMPED CIRCUIT MODEL

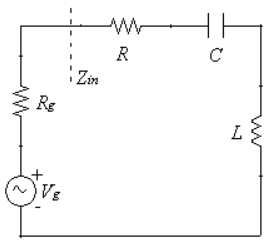
A. Circuit model of electrically small spherical helical antenna

The electrically small spherical helical antenna of N turns whose maximum dimension is less than 'radian length' ($\lambda/2\pi$) is considered, Fig. 1. There are various possibilities for wounding wire around a sphere, and the direction vector is given by:

$$\vec{l} = \vec{\theta} + \sin\theta \frac{d\varphi}{d\theta}\vec{\varphi}. \qquad (1)$$



a)



b)

Figure 1. a) Geometry of spherical coil and b) the equivalent circuit

The electromagnetic field of spherical antenna is solved analytically in [14] for a wide class of functions $\varphi = \varphi(\theta)$ in a form of the series of spherical wave functions using the Debye potentials. Here we examine the antenna with equidistant turns where (n = 0, m = –0.5 in eq. (4) from [14]):

$$\varphi = 2N\theta. \tag{2}$$

The following analysis was performed by Wheeler without using spherical vector wave functions (used by Chu [15], Mei [14] and others) based only on equivalent circuit model of the small antenna. His work has been verified analytically and experimentally [16, 17].

Inductance of spherical coil with equidistant turns in air surrounding medium with magnetic medium filling (μ_r) is given as [12]:

$$L = \frac{2\pi}{9}\mu_0 a N^2 \frac{3}{1+\frac{2}{\mu_r}} \tag{3}$$

where a is coil radius and N number of turns. For two identical coaxial coils in free space the mutual inductance is given by [12]:

$$M = \frac{2\pi}{9}\frac{\mu_0 a^4 N^2}{r^3}, \tag{4}$$

where r is the distance between centers of coils. If the coils are coplanar, the mutual inductance is ½ M. Small spherical helical antenna radiating spherical TE_{10} mode is represented as a series RLC circuit (Fig. 1 b)) because it behaves as a magnetic dipole whose stored magnetic energy is much greater than stored electric energy. Thus the series capacitor, used as a tuning element to bring the antenna to resonance, can be calculated from the resonant frequency:

$$\omega_0 = \frac{1}{\sqrt{LC}}. \tag{5}$$

It can be noted from (3) and (4) that the resonant frequency of spherical coil will be changed by some factor according to the change of radius and pitch angle. This will be examined in Section III.

Radiation resistance can be obtained from:

$$R = 20\left(\frac{2\pi\sqrt{A}}{\lambda}\right)^4 \tag{6}$$

where

$$A = \frac{2\pi}{\left(1+\frac{2}{\mu_r}\right)} r^2 N \tag{7}$$

It follows that Q factor is obtained as the ratio of the volume of 'radian' and physical sphere multiplied by the shape factor ($1 + 2/\mu_r$) [12]:

$$Q = \frac{\omega L}{R} = \frac{1}{(kr)^3}\left(1+\frac{2}{\mu_r}\right) == \frac{V_{radian\ sphere}}{V_{physical}}\left(1+\frac{2}{\mu_r}\right) \tag{8}$$

Wheeler was the first to show that as the physical antenna size decreases, the ratio of reactance to radiation resistance increases leading to high Q factor [12, 18]. Note that (8) means that different antennas enclosing the same minimum sphere will have different Q values depending on how their geometries utilize the same volume.

B. Circuit model of WPT system

The equivalent circuit of the WPT system with two resonant spherical helical antennas is depicted in Fig. 2. The left side of the equivalent circuit shows the transmitting antenna linked magnetically by mutual impedance M with receiving antenna on the right side. The resonant transmitting spherical antenna is modeled as an inductor with inductance L_{tx}, capacitance C_{rx} and radiation resistance R_{tx} (when using copper wire this resistance is higher due to additional ohmic losses). The receiving antenna is modeled in the same way and it is loaded with R_l.

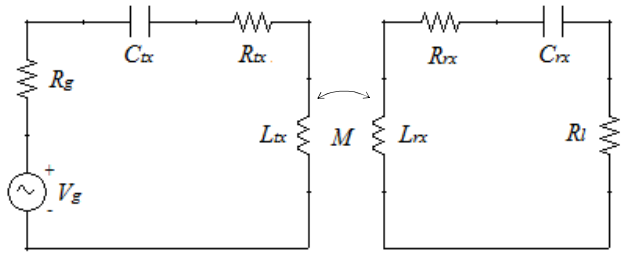


Figure 2. The equivalent circuit of the WPT system

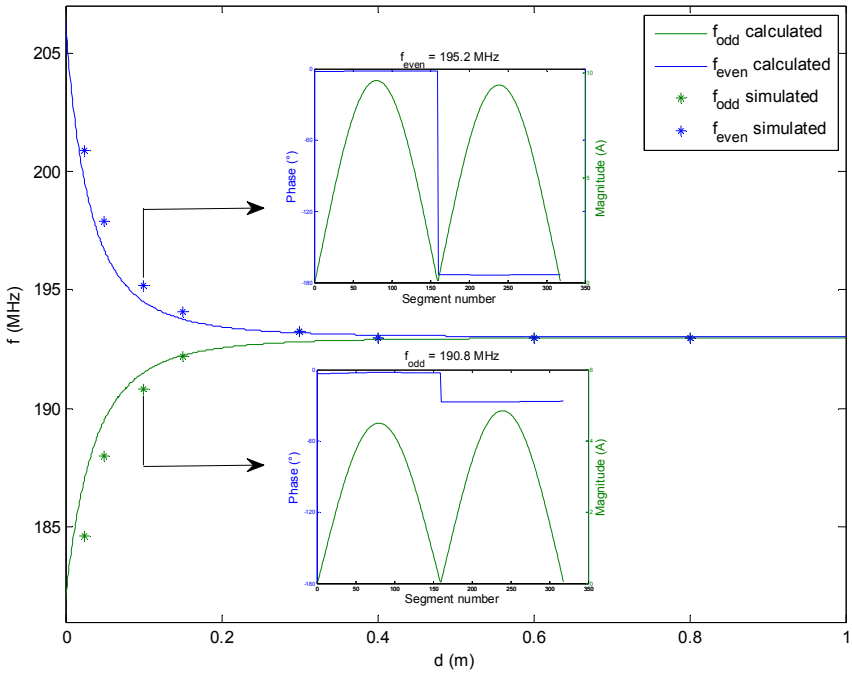

Figure 3. The coupling between two coaxial PEC spherical helical antennas with D = 10 cm and N = 3.8 turns

The most important factor in WPT system design is M as it varies with distance between resonators and it is directly related to coupling coefficient and power transfer efficiency. Based on coupling resonator theory [8-11], coupling coefficient k can be calculated as:

$$k = \frac{M}{\sqrt{L_{tx}L_{rx}}} = \frac{f_e^2 - f_o^2}{f_e^2 + f_o^2}, \tag{9}$$

where, assuming the lossless circuit elements, f_e and f_o are the even and odd mode resonant frequencies of two resonant spherical helical antennas, respectively. The phenomenon of coupling is illustrated in Fig. 3, where the results of simulations (see Sec. III.) are compared to the calculations by Wheeler formulas (3) and (4), and (9).

As the separation distance increases, the coupling between the resonators decreases as well as the frequency separation. When frequencies f_e and f_o converge to one, the system is at critical point $k_{critical}$ at which the mutual inductance becomes negligible and the antennas can be regarded to be independent of each other. The system is in over-coupled mode when $k > k_{critical}$ where almost constant high efficiency can be achieved at any distance (below the critical one) by selecting the accurate frequency, i.e. by tuning. The currents of two spherical antennas are of the same magnitude and almost in phase at f_o, while at higher mode frequency f_e they are out of phase. This is depicted in upper (f_e) and lower (f_o) diagrams in Fig. 3 where green line represents the current magnitude and the blue line its phase. When system is in under-coupled mode for $k < k_{critical}$, the power transfer to the load is decreasing with distance.

Impedance mismatch over short separation distance between transmitter and receiver is one of the key technical issues in WPT systems. The performance of WPT system can be greatly improved by compensation methods using adaptive frequency control circuit or tunable impedance matching circuit [11].

III. SPHERICAL HELICAL ANTENNA COUPLING

In this section, the simulation results of resonant WPT using spherical helical antennas with different geometry properties and loads are presented. The simulations are carried out using numerical software NEC and FEKO based on Method of Moments (MoM). By changing the separation distance (air gap) between two identical antennas we examine the power transfer efficiency which is calculated as the ratio of the power dissipated at the load of the receiving antenna and the power accepted into the transmitting antenna:

$$PTE = \frac{R_l |I_{rx}|^2 / 2}{R_{in} |I_{tx}|^2 / 2}, \tag{10}$$

where R_l is load resistance, R_{in} the input antenna resistance, I_{rx} the current at the load and I_{tx} is the current of the feed point of the transmitting antenna. Equivalently, PTE can be calculated from S-parameters obtained by simulation or measurements [6] as:

$$PTE = \frac{|s_{21}|^2}{1 - |s_{11}|^2} \tag{11}$$

Spherical helical antennas with different loads are examined and the results are shown in Fig. 4. The antennas are in coaxial configuration. The wire radius is r_w = 0.2 mm and it is perfectly conducting (as in all other

simulations if not specified otherwise), D = 10 cm and N = 3.8 turns.

The optimal load for maximum power transfer at resonant frequency of a standalone antenna in free space is calculated using Linville method [19] and utilized at each separation distance. When the load resistance is matched to the resistance of the standalone antenna in free space (the system is in resonance so the antenna input impedance is a pure resistance), the PTE is at its maximum in under-coupled region. Impedance mismatch due to the mutual inductance in over-coupled region (compensated by conjugate-matching in Linville method) lowered the PTE when utilizing fixed load. For practical purposes, a 50-Ω load is simulated for the case of PEC and copper wire with the same wire radius. The impedance mismatch between the antennas is the worst in the case of 50-Ω loading (except for small distances). PTE is even more decreased when using copper wire due to increased ohmic losses.

Considering geometry parameters, let us first examine the spherical helical antennas occupying the same physical sphere with diameter D = 15 cm, Fig. 5. The receiving antenna is loaded with 50-Ω resistance. With greater wire length (increasing number of turns N) the PTE vs. distance increases while the resonant frequency decreases. Maximum PTE at some distance d (m) can be achieved at 17.53 MHz. For the same physical volume the antennas with decreasing 'radian' sphere, achieve lower Q factor (see eq. (8)) and better PTE results. Also, it can be noticed that the resonant frequency changes proportionally to the decrement of number of turns, as $f_{01}/f_{02} \approx N_2/N_1$ (for the same sphere diameters) due to different coil inductances (see eq. (1)).

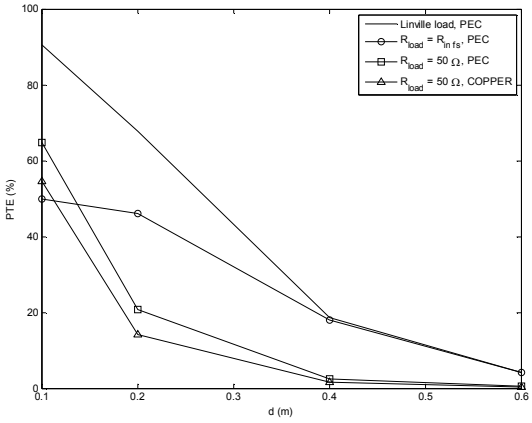

Figure 4. PTE of spherical helical antennas at f_0 = 193 MHz with D = 10 cm, N = 3.8 and different loads

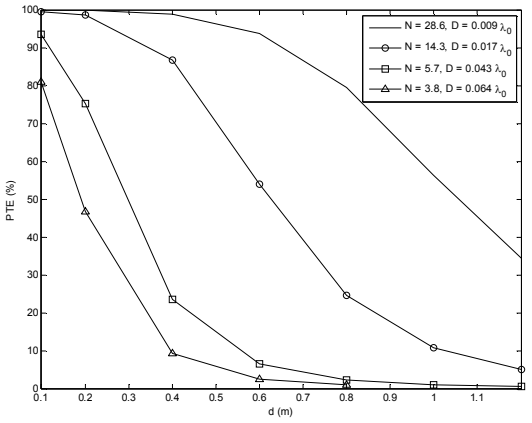

Figure 5. PTE of spherical helical antennas enclosing the equal volumes, D = 15 cm and R_l = 50 Ω

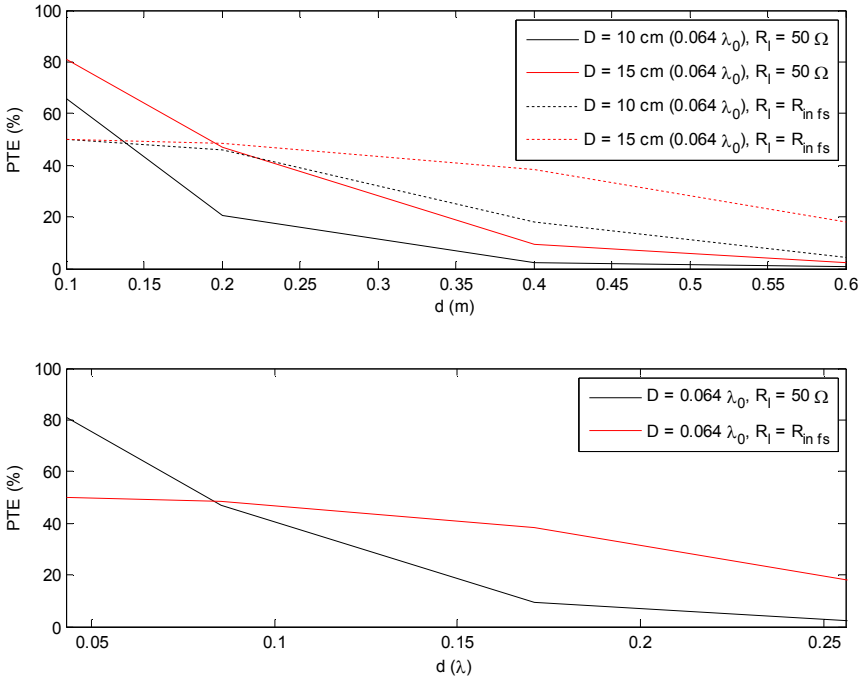

Figure 6. PTE of spherical helical antennas enclosing the same 'radian' sphere in d (m) and d (λ)

Then, we observe the antennas that occupy the same 'radian' sphere. Fig. 6 shows the results of PTE vs. d (m) and d (λ) for N = 3.8 and $R_l = R_{infs}$. Using the spherical helical antennas with different diameters and the same number of turns, the resonant frequency can be calculated roughly from the dependence on coil's diameter, as $f_{01}/f_{02} \approx D_2/D_1$ (for the same number of turns). So, we can derive an approximate formula for calculating the resonant frequency of any spherical helical antenna if geometry properties (D and N) and resonant frequency of one spherical antenna are known:

$$f_{02} \approx f_{01} \frac{D_1 N_1}{D_2 N_2} \tag{12}$$

Higher power transfer over the physical antenna separation d (in meters) is achieved with physically larger antenna with longer wire and lower resonant frequency for both loads at the receiving antenna R_l = 50 Ω and $R_l = R_{infs}$. These results agree with Wheeler's conclusions that Q factor of electrically small antennas decreases when volume of the antenna increases (so it is possible to achieve higher PTE vs. d(m)). Also, similar conclusion can be drawn from simulation results in Fig. 5. The antennas which best utilize the same volume (those with higher number of turns) tend to have smaller Q, i.e. achieve better PTE results for d (m). Due to a better match antennas loaded with $R_l = R_{infs}$ achieve higher PTE for the gaps larger than 20 centimeters.

The resulting PTE vs. d (λ) is the same for both antennas when using the same 'radian' sphere. The overall PTE vs. d (λ) is higher and shows a slower decay when loading the antenna with $R_l = R_{infs}$. Also, it is important to note that the antennas occupying the same 'radian' sphere have the same radiation resistance depending only on antenna enclosing sphere in electrical dimension.

IV. CONCLUSION

WPT system with spherical helical antennas and different loads is analyzed using equivalent circuits and electromagnetic analysis. Different loads at the receiving antenna illustrated the matching problem as the key problem of the WPT systems. Also, the effect of geometry properties of spherical helical antenna on power transfer efficiency is investigated where approximate formula is found for calculation of spherical helical antenna resonant frequency if resonant characteristics of one antenna are known. Spherical helical antennas occupying the same physical and 'radian' volume are compared. Wheeler's conclusions on small antennas are confirmed in terms of power transfer efficiency.

The results show that the antennas that best utilize the same physical volume (with greater number of turns or longer wire length), achieve better power transfer efficiency over separation distance in meters. However, one must also consider that a longer wire means a higher antenna resistance that lowers the antenna efficiency and, consequently, the WPT performance.

Abstract - A power consumption of a high performance computer (HPC) system has been an issue lately. Many programming techniques are still relying on performance gain, but only few of them are concerning energy footprint of the increased computing power. MPI and OpenMP are considered as a core scientific HPC programming libraries for distributed-memory and shared-memory computer systems respectively. Each of them brings performance when used on a parallel system, but there are dissimilarities in their performance per watt ratio. The key is to find the best appliance for each of them on a shared-memory computer system.

Keywords: High performance computing, green computing, parallel programming

I. INTRODUCTION

The performance race in a world of High Performance Computing (HPC) came to a breaking point, because in a world of limited resources that kind of growth is not feasible. More concerning facts occupy the platform providers, like the running costs, reliability, availability and overall profitability of running HPC installations. The performance is still a key point and the purpose of HPC, thus said by the term, but "performance no matter what" is not. When the group of scientists made a "Green destiny" HPC project at 2001, [1], the HPC world was on the verge of turnaround. Immediately after, all of the HPC providers started to think in a way not only to offer performance, but to offer best performance per energy consumed. That direction brought two advantages, first was obviously greater environment friendliness, and the second was bigger revenue for the HPC providers. However, the change of HPC philosophy is only the first step in creation of ultimate systems with high performance per energy consumed, because there are still many issues to solve. The existing HPC world has to be changed from bottom to top, meaning that everything has to be adapted to the new state of the art. Changes have to be applied from IC levels to cooling, and programmer consciousness of the resource utilization, as presented in [2]. In this manner, the Green500 list has increasing popularity over a Top500 list of HPC ranking, thus influencing awareness of a power consumption problem in a HPC world.

When speaking of tuning the HPC efficiency, it is obvious that the important step is tuning up the tier 5 of the abstraction layer based on [2], which means selecting the parallelization models which bring the most efficient performance. Considering that an HPC node is a shared-memory computer system, often capable of executing parallel job by itself, and the increasing use of hybrid parallel programming technique, it can serve as a standalone platform for efficiency testing. Furthermore, the two most represented parallel scientific paradigms are message passing and thread programming; therefore it is important to compare their mostly used representatives: OpenMP for thread programming, and MPI for message passing paradigm. So in this paper we address an aspect of using these two technologies on a shared-memory computer system comparing whether there are significant differences which could be used to improve energy efficiency of an HPC systems.

The rest of the paper is organized as follows: Section II presents some of the related work on the Green HPC research which led to some of the ideas in this paper. Section III analyzes existing green metrics for the HPC power and performance evaluation and chooses best for the experimental evaluation. Furthermore, Section IV aggregates some of the most important differences between OpenMP and MPI programming APIs in order to clarify the experimental results, while Section V explains the rest of the experimental setup. Section VI presents the experimental results and analyzes them, whilst section VII presents plans and ideas for related future research by the authors. Finally, Section VIII concludes the paper.

II. GREEN HPC

The era of greening the computing resources is mostly aimed at HPC systems because of their enormous energy footprint. For instance, a present leader of a Top500 supercomputer list – Japanese K computer – delivers 11.28 PFLOP/s but at 12,66MW of power consumed. That led to many publications in the field of green computing technologies, an area of research which is constantly growing and is already vast. Therefore, this section describes only a portion of related work narrowly related to the topic of this paper.

The similar experiment has been conducted by the authors in [3]. They have done a series of tests comparing the performance per watt metric on the multi core CPU, GPU and a combination of both. Their goal was to achieve best possible performance per watt using the ideal combination of CPU and GPU load. Although, their measurement depends on the component power draw, most of which are estimated (CPU power draw from MBO, GPU

power draw from PCIe slot), thus making room for some errors.

Furthermore, the green metric for HPC systems is discussed in [4], where authors try to implement other metric for measurement the "greenness" of the HPC system than the most popular performance per watt (FLOPS/W). Their metric, borrowed from low-power circuit design called Energy Delay product, ED^n, failed to achieve its purpose of equally classifying computer systems under the green metric. The parameter n, which is the emphasis on performance over power consumption, achieves its purpose only if set to 1. Otherwise the metric prefers only highly parallel supercomputers, almost independent on their power draw, thus making the parameter n redundant. Consequently, authors use FLOPS/W metric, although they stress out the importance of green metric improvement.

The authors in [5] expand the metric from [4], and use other methods in order to standardize the power/performance measurement for Green500 list. Also, the authors analyzed power measurement procedures, stating that instantaneous power measurement can have up to 35% variance over the entire run of the application. But this variance is not an issue in majority of performance per watt tests, because only a mean value is of importance there. However, if the reliability and availability is an issue, these facts should be taken into account.

The theoretical comparison between OpenMP and MPI programming paradigms is presented in **Error! Reference source not found.**, with the important accent on behavior on single servers (shared-memory platforms, SMPs). Authors mention that application is the key of choosing either approach, because both paradigms can have different efficiencies while used in different applications running on an SMP.

III. METRIC

The key for a successful benchmarking of the HPC power efficiency is the right metric. Undoubtedly, the most important green metric for an HPC system is the amount of processing ability per electricity consumed, or more popularly known as performance per Watt. As in Section II there are some attempts to expand this metric, but most of the authors, vendors and providers rely on FLOP/Ws, which is an equivalent to FLOP/J (Floating Operations, or just Operations, per Joule), (1).

$$\eta = \frac{\text{Number of operations}}{1\,\text{Joule}} \tag{1}$$

The metric from (1) is also used in ranking the Green500 list, [7]. Furthermore, (1) can be viewed as a form of the energy delay product, explained in [4], considering $n = 1$ (which means that the emphasis on performance and power saving is equal), shown by (2).

$$ED^n\left[\frac{\text{FLOP}^{\,n}}{Ws}\right] = \eta, \quad n = 1 \tag{2}$$

Another metric which is used to analyze performance per watt of an HPC system is J/Operation (Joule per Operation), or commonly nJ/FLOP, like in [8]. Generally, the power of a computer system is measured as the instantaneous real power, which is the power turned to useful computational work.

Real power of a complete system is polled in intervals of approximately 1s, and is the best indicator of the current load of the system. The aforementioned metric will be used in Section VI when explaining experimental results.

IV. OPENMP VS. MPI

Message passing and thread programming paradigms (mostly in the form of two technologies - MPI and OpenMP) tested in this experiment are the main tool for scientific applications requiring parallelism. In this paper we compare these two technologies in respect to energy efficiency, because a goal of greening the HPC systems cannot be achieved without greener applications.

MPI is an API or a programming library that allows processes in FORTRAN, C and C++ to send messages to each other. OpenMP, on the other hand, is not an API, but an extension to a compiler, as noted in 0. While MPI creates independent processes, OpenMP uses operating system threads (POSIX threads or Pthreads) running at the same time and sharing memory space. As a result, MPI is aimed (but not restricted) to the use in distributed-memory systems, while the OpenMP is exclusively made for the use in shared-memory environments. Therefore, using MPI in shared-memory environments does not seem practical, although the experiments show otherwise.

If a single process needs to read the data to which another process has access to when using MPI, a message has to be sent between them. OpenMPs threads work differently; they can achieve the same by reading from the same memory locations, but not at the same time. At first glance thread programming seems more efficient when used on a shared-memory platform than sending messages between the two processes. However, it all depends on the application. Sometimes is better to send messages than to wait for shared-memory access, mostly in applications with many shared variables. Therefore, MPI spawns multiple independent processes, each carrying its own code, while OpenMP uses single process which spawns multiple threads. A combination of the two is possible, which is the topic for future work.

There is an extension to MPI when running on a shared-memory platform which uses shared-memory process model (SMPM) shown in [9]. This MPI extension is made because, as authors say, direct load/store access between processes is more efficient than any of MPI communication methods and easier to use than threads. The SMPM MPI emulates shared-memory behavior via calls for allocation and deallocation of a shared-memory space. Nevertheless, a classic message passing system is used in this paper; the analysis of the introduced SMPM MPI extensions is a part of the future research.

V. TEST SETUP

So as to achieve better insight into programming paradigm influence on the power efficiency of an HPC system, the three most important aspects of the test setup had been analyzed: algorithm (which serves as the computational

load), test platform (a computing system which will run the algorithm), and the power measurement equipment. Our test setup comprises different platforms, different metrics and different loads.

A. Algorithm

The testing algorithm is an MxM operation (matrix multiplication), shown by (3).

$$\mathbf{C} = \mathbf{A} \times \mathbf{B}, \quad \mathbf{A}, \mathbf{B} \in R^{n \times n} \tag{3}$$

Matrix multiplication is a large scale SIMD operation, which consists of add and multiply operations. Many HPC benchmarks rely on highly optimized routines for MxV and MxM operations from parallel libraries such as PBLAS and SCALAPACK. Therefore, the matrix multiplication can be considered as a sort of an HPC benchmark. The complexity of such an algorithm is $O(n^3)$ for square matrices, although there are other newer methods which achieve lesser complexity, such as generalized Coppersmith–Winograd algorithm, [10], complexity of which is $O(n^{2,3727})$. But, considering that the algorithm is needed only to put a high computational load to the processing units, the standard algorithm is a good option.

B. Testing platform

The three completely different platforms were used for performance evaluation: the Processing Platform 1 (PP1), PP2, and PP3, details of which can be seen in the Table I. However, only the first two served as a platform for the power efficiency tests. All platforms are based on Linux OS with the gcc compiler installed on all of them, furthermore, programs were run directly through terminal on PP1 and PP2, and through Condor-G job submission script on PP3.

C. Power measurement

We use National Instruments' NI DAQPad-6015 for data acquisition, Tektronix A622 current probe and IOtech WBK61 voltage probe. For the data analysis and oscilloscope reading we use LabView 9.0.

VI. Experimental Results

For the performance testing matrices sized from 2000x2000 to 5000x5000 with increments of 500 per dimension were used. Smaller matrices were negligible for good performance comparison, so they were omitted. Bigger matrices, on the other side, cause very long execution times, which is not feasible on platform PP1. Matrix size of 3000x3000 was used for power efficiency test, because this dimension proved itself to be the best tradeoff between execution time and system load for recording the power profile of the system load. Also, the authors in [3] used similar dimension, which makes it easier to compare results with them. Tests are divided into two separate subsections for better analysis. The first subsection shows matrix multiplication performance results using differently sized matrices on different platforms, while in second subsection power measurement analysis has been given.

TABLE I. Platforms used in the experiment

ID	*Description*
PP1	Single core Intel P4 CPU @ 2.4GHz, 1GB of DDR RAM @400MHz
PP2	Dual core AMD Athlon CPU @ 3.13GHz, 4GB of DDR2 RAM @ 1000MHz.
PP3	Single CRO-NGI ETFOS node (PowerEdge M600 Blade), two Quad-core Intel Xeon Processors E5430 @ 2.66 GHz, 16GB of ECC DDR2 RAM @ 667MHz

A. Performance

Fig. 1, 2 and 3 show the difference between raw performance of the OpenMP and MPI on platforms PP1, PP2 and PP3 respectively, measured in seconds. We measured an average execution time difference of 15% running at PP1, 25% running at PP2 by using single core, and 27% by using both cores in favor of the MPI. PP3 platform results are even more favorable to MPI, showing the difference of 4% when running on single core, 84% running on 2 cores and 116% running on all 8 cores. The differences occur because of the better resource utilization by the MPI, better task separation, and probably the imperfections of the POSIX thread resource control (in the case of OpenMP). Also, given results tend to question other parameters which may cause the differences which occurred, such as the type of benchmark algorithm used to stress the system, MPI and OpenMP versions, the nature of OpenMP programming approach, etc. Therefore, we plan to conduct more tests which will confirm or reject these doubts.

B. Power consumption

The main point of making this paper is the energy footprint study for the message passing and threads paradigms. The results prove that efficiency also goes in favor of MPI. Fig. 4 illustrates power profiles while running the algorithm from subsection V.*A.* on platforms PP1, PP2 using single core, and on PP2 using both cores respectively. Platform PP3 was not analyzed because of the momentary unavailability of node power data, but it will be the part of our future work. Even considering the lower power consumption of a computer system while using OpenMP, the difference is not enough to compensate for the longer execution times, resulting in a lower performance per watt figures, which will be explained hereinafter. Energy efficiency graph displayed in Fig. 5 shows that the MPI is more effective than OpenMP tested on 2 platforms. The difference in MFLOP/J ranges from 11.5% for PP2 while using both cores, to 12% for single core run at PP2, up to 16% on PP1. The difference is far from negligible, leading

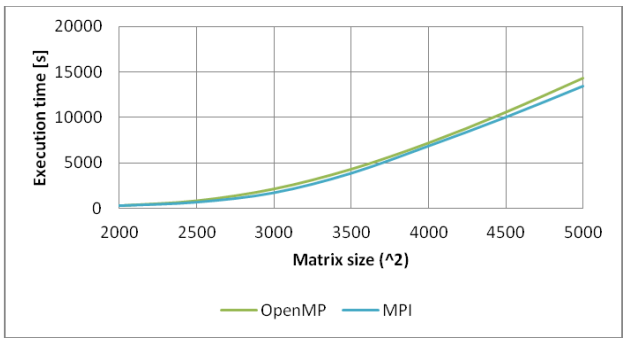

Figure 1. PP1 performance.

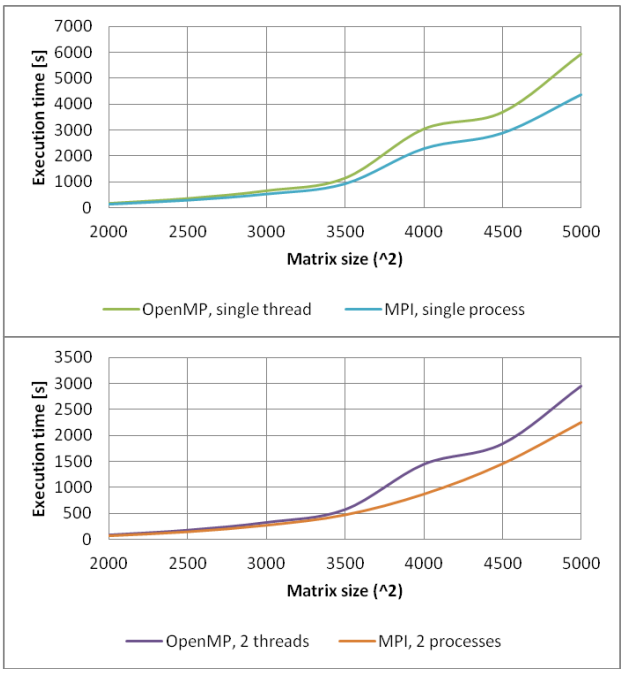

Figure 2. PP2 performance

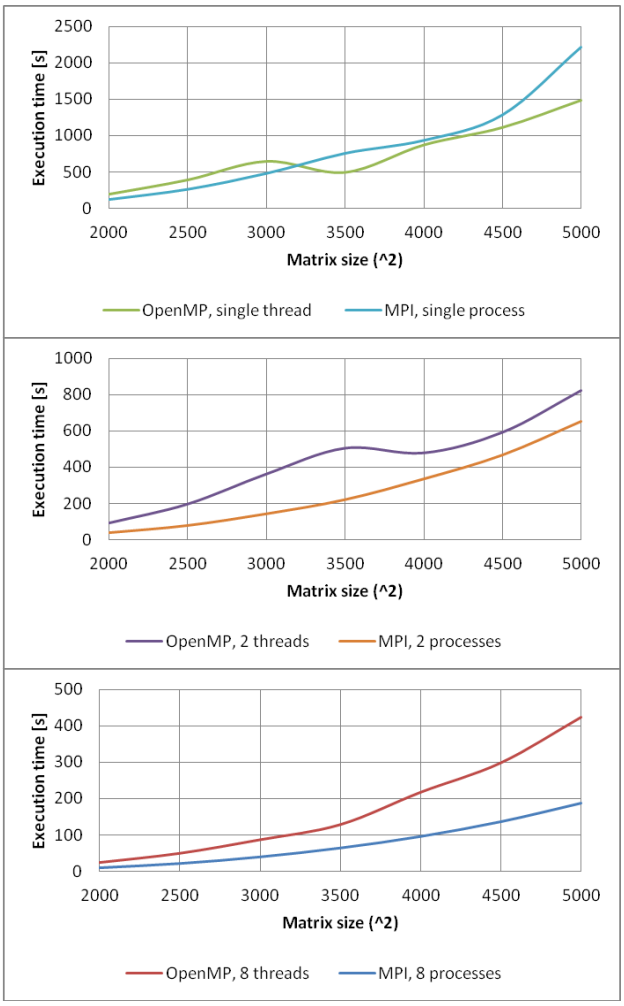

Figure 3. PP3 performance

to the conclusion that, although OpenMP is intended exclusively for the shared-memory platform, it is not necessarily a better option compared to the MPI. The top efficiency achieved was 0.982 MFLOP/J (1.03 μJ/Operation), by MPI using both cores on PP2. OpenMP scored lowest efficiency in our experiment of 0.353 MFLOP/J (2.83 μJ/Operation), running at PP1. These results put tested platforms far behind the efficiency of modern HPCs, but they serve as a good setup for testing the energy footprint of the parallel programming paradigms.

VII. Future Work

Our goal is to further expand the influence of parallel programming paradigms and technologies on the HPCs energy footprint. Our future work will also encompass new platforms and different algorithms. Furthermore, we plan to conduct an energy analysis more thoroughly, by measuring more parameters whose setting can significantly affect HPC energy efficiency.

VIII. Conclusion

The two most frequently used parallel programming technologies such as OpenMP and MPI share common purpose, but at very different cost. Although the MPI standard was primarily made for distributed-memory architectures, which is contradictory to OpenMPs use on shared-memory architectures, our experiment shows that this is not always applicable. By using the common HPC benchmark algorithm – matrix multiplication, we have shown that OpenMP lacks performance when running large scale SIMD operations on shared-memory computer system when compared to MPI. Albeit using shared-memory extensions for MPI, it proved itself superior over OpenMP not only in the field of performance, but in the field of performance per watt. This conclusion changes the perspective of green HPC, because small energy efficiency difference on single shared-memory node can ultimately lead to immense power differences on large scale applications and HPCs.

***Abstract*—In this paper we analyze the performance of a multiprocessor using a virtualized environment. There are a lot of papers analyzing the performance with conclusion that discrepancy happens due to L2 cache. Our conclusion based on observation and experimental research shows that the main reason should be L3 in this case.**

Our hypothesis to be confirmed by experimental research is that the program will be executed slower in virtual environment compared to traditional server. There is also a hypothesis that the speedup in virtual environment for parallel execution is smaller than in sequential. However, analyzing the speedup graphs we can conclude that speedup in virtual environment is greater than speedup in traditional environment. We have also found that there is a region with particular problem size for matrix multiplication where the program runs faster in virtual environment.

The experiments showed that the achieved performance in virtual environment is even better than traditional environment, but only in specially defined regions. In other regions there is a huge performance drawback in virtual environment and fails to measured average of 66.58% of traditional environment.

***Index Terms*—High Performance Computing, Parallelization, Cache, Memory, Virtualization**

I. Introduction

Virtualization offers creation of more dynamic, flexible and scalable datacenters. It is the baseline for cloud computing IaaS and PaaS service layers. Cost reduction for power consumption and cooling, easy administration, backup, migration, and security isolation are benefits and reason why virtualization techniques are more and more used in modern enterprises.

Despite all the advantages, current virtualization solutions do not produce performance isolation among virtual machines. The introduction of a new layer produces overall performance discrepancy of the application in a guest operating systems. Figures 1 and 2 present the architecture differences of traditional and virtual environment. Most of current multiprocessors use shared last level cache. Sharing it among different guest operating systems produces much more cache misses rather than traditional.

The key expectation of a multiprocessor is achieving maximum efficiency offered via high performance computing. Our intention is to analyze the resource utilization for computationally and memory intensive algorithm execution with high performance computing in virtual environment. An example of computationally and memory intensive algorithm is the matrix multiplication algorithm.

Fig. 1. Traditional environment [1]

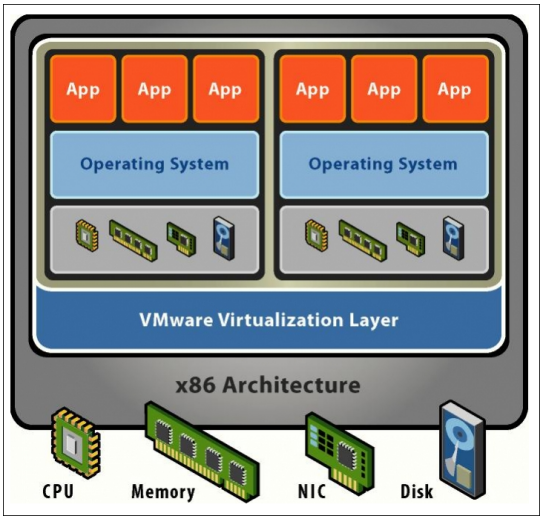

Fig. 2. Virtual Environment [2]

A. Related Work

A lot of papers refer the virtualization performance. Padala et al. evaluate Xen and OpenVZ virtualization technologies

focusing on CPU efficiency in various configurations [3]. They conclude large performance discrepancy caused by higher virtualization overhead in Xen, likely due to higher L2 cache misses and misses per instruction. In this paper we prove that performance discrepancy is not due to L2 cache, but due to last level cache, i.e. L3 in this case.

Koh et al. [4] predict the performance scores of the applications under performance interference in virtual environments. They describe the phenomenon that running the same virtual machine on the same hardware at different times among the other active virtual machines will not achieve the same performance. That is, the performance of the virtual machine depends on the work performed by other active virtual machines. Therefore, we use only one virtual machine with the same hardware as real machine to measure the performance drawbacks caused only due to virtualization overhead layer.

A lot of research is performed on high performance computing (HPC) and better resource utilization. The authors in [5] found a superlinear speedup in virtual environment executing the matrix multiplication algorithm in a multi chip single core. The series of experiments which increase the matrix size N versus the number of processing elements P can be found in [6]. In this paper we analyze multi chip multi core virtual environment and compare the performances obtained in virtual and traditional environment on the same hardware infrastructure.

Combining HPC with virtual environment is also analyzed. Performance models for applications in virtual environments are build in [7]. The authors in [8] evaluate the performance of several virtual machine technologies with OpenMP and MPI jobs. They concluded smaller speedup in all virtual test environments for parallel execution with OpenMP on 2x4 cores. The results of our experiments with matrix multiplication algorithm show greater speedup in virtual environment compared to traditional when executing in parallel. Distributed memory over committed system is analyzed in [9]. The authors improve the communication performance by avoiding the waste of processing resources on unnecessary message polling.

The paper is organized as follows. In Section II we briefly present the test plan and methodology. The matrix multiplication algorithm is used for performing the testing as presented in Section III, along with the analysis of computational and memory complexity in sequential and parallel execution. The results of the experiments in traditional and virtual test environments are presented in Sections IV and V correspondingly. Section VI compares the results of the experiments performed on both environments. In Section VII we discuss the results of achieved performance discrepancy in virtual environment.

II. Testing Methodology

The experiments are performed on two same HP Proliant DL380 G7 servers, each with 2 x Intel(R) Xeon(R) CPU X5680 @ 3.33GHz GHz [10] and 24GB RAM. The processor has 6 cores, each with 32 KB 8-way set associative L1 cache dedicated per core, and 256 KB 8-way set associative L2 cache dedicated per core. All 6 cores share 12 MB 16-way set associative L3 cache.

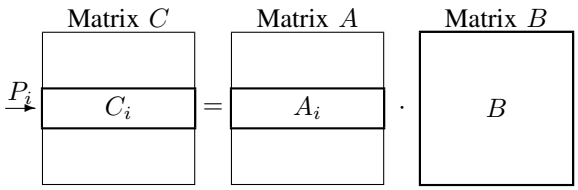

Fig. 3. Parallel Matrix Multiplication [6]

The first server is installed with Linux Ubuntu 10.10 as traditional host operating system on one real hardware machine. The second server uses Linux Ubuntu 10.10 installed as guest operating system with all resources dedicated to the virtual machine using VMware ESX Server 5i [11].

Execution time is measured for the matrix multiplication algorithm on both traditional and virtual servers during the test experiments.

The test experiments have two goals. The first goal is to model the multiprocessor's behavior, i.e. speed and speedup in computationally and memory intensive matrix multiplication algorithm on both environments as a baseline. The second goal is to model the performance drawbacks due to virtualization implementation on the second server compared to traditional server.

III. Testing Algorithm

Matrix multiplication algorithm is used as test data. To simplify, we choose squared matrices with dimension N. For all $i, j = 0, 1, \ldots, N-1$ the result product matrix $C_{N \cdot N} = [c_{ij}]$ is defined in (1) by multiplying the multiplier matrix $A_{N \cdot N} = [a_{ij}]$ and the multiplicand matrix $B_{N \cdot N} = [b_{ij}]$.

$$c_{ij} = \sum_{k=0}^{N-1} a_{ik} \cdot b_{kj} \tag{1}$$

We partition the matrix A on N rows and each row C_i of matrix C is calculated as defined in (2) and depicted in Figure 3.

$$C_i = A_i \cdot B \tag{2}$$

To exploit maximum performance for parallel execution on P processing elements we group rows A_i in P sets, such that for all $i = 0, 1, \cdots, N-1$ and $s = 0, 1, \cdots, P-1$ row A_i is placed in Set_s if equation (3) is satisfied. The algorithm assures that each row A_i will be placed in exactly one set.

$$s = i \ mod \ P \tag{3}$$

Each set Set_s is sent to execution on the processing element P_s.

All test cases are executed using different matrix size N for different number of processing elements from 1 to 12. Tests are performed by unit incremental steps for matrix size and number of processors.

Matrix multiplication algorithm is computationally and memory intensive and depends of matrix size N.

A. Computational Complexity

The algorithm performs N^3 sums and N^3 products, or total $2 \cdot N^3$ operations for sequential execution on one processing element.

The matrix partitioning algorithm explained previously defines different data and code for each processing element in parallel execution. Each processing element in parallel environment executes average $2 \cdot N/P \cdot N^2$ operations. In total the algorithm performs $2 \cdot N^3$ operations for parallel execution, i.e. same as sequential execution on one processing element.

B. Memory Complexity

The algorithm needs to store $3 \cdot N^2$ elements. If ME denotes the size of one matrix element in bytes, then total memory requirement is $3 \cdot N^2 \cdot ME$ for sequential execution. Cache memory does not need to store three matrices but only two input matrices A and B since the write is directly forwarded to main memory. No matter what cache memory type the processor uses it needs to store $2 \cdot N^2 \cdot ME$ bytes.

Due to shared memory parallel system, last level memory (L4 or main memory in this case) needs to store the whole matrices A, B and C, or total $3 \cdot N^2 \cdot ME$ bytes. Opposite to sequential execution the cache memory requirement directly depends on cache type and level for parallel execution.

Dedicated cache memory per processing element (core) needs to store the whole matrix B with capacity of $N^2 \cdot ME$ bytes and only chunk of matrix A. The amount of necessary space in dedicated per core cache memory is given in (4).

$$DedicatedCachePerCore = (1 + 1/P) \cdot N^2 \cdot ME \quad (4)$$

L3 cache is usually shared per chip if exists. If s denotes the number of chips the shared multiprocessor consists, then L3 needs to place the whole matrix B with $N^2 \cdot ME$ bytes and around N^2/s elements of matrix A, i.e. around $1/s \cdot N^2 \cdot ME$ bytes. The total amount of necessary space in dedicated per chip cache memory is given in (5).

$$DedicatedCachePerChip = (1 + 1/s) \cdot N^2 \cdot ME \quad (5)$$

Our test environment uses L1 and L2 dedicated per core caches. Each L2 cache should be able to store $DedicatedCachePerCore$ bytes defined in (4). The multiprocessor uses $s = 2$ chips with dedicated per chip L3 cache and thus each L3 cache needs to store $DedicatedCachePerChip$ bytes defined in (5).

C. Algorithm Parameters

The processor speed is calculated by dividing the number of operations and measured execution time (6), both for sequential and parallel execution.

$$Processor\ Speed = \frac{2 \cdot N^3}{T_{measured}} \quad (6)$$

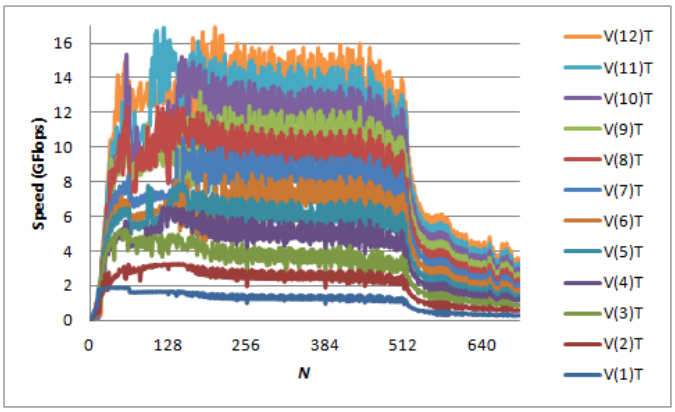

Fig. 4. Speed in Traditional (T) Operating System

Speedup for parallel execution is calculated as ratio of sequential and parallel execution time by (7).

$$Speedup = \frac{T_{Seq}}{T_{Par}} \quad (7)$$

Our hypothesis to be confirmed by experimental research is that virtual environment will perform bigger execution time and smaller speed, as well as smaller speedup compared to traditional server.

D. Testing Regions

The authors in [6] define regions L1, L2, L3 and L4 as follows. The region L1 is determined as memory size of the L1 cache and its capability to store complete memory requirements. It means to find the maximum N which will fit in (4). It is assumed that in this case no cache miss will be generated in L1 cache since all relevant data will be stored in the cache. Increasing N will produce cache misses, but now we enter the L2 region where we try to find the value of N that will enable storage of all memory requirements in L2 and avoid generation of cache misses on L2 level. The same definitions continue to explain L3 and L4. If next cache level is missing it is assumed that main memory presents the corresponding region.

The experiments show different behavior in all defined regions. A good analysis of the obtained results will define overall behavior of testing environment.

IV. Parallel Matrix Multiplication in Traditional Environment

This Section presents the result of the baseline experiments in traditional environment. Figure 4 presents the speed expressed in gigaflops versus matrix size N for each test case with different number of processing elements $P = 1, 2, \cdots, 12$. Figure 4 presents huge performance degradation when $N > 512$. This is the entrance in L4 region, i.e. the region where the matrix elements do not fit in last level L3 cache generating cache misses in L3 cache. In this region the matrix elements should be loaded from the main memory, instead of L3 cache, which is time consuming operation.

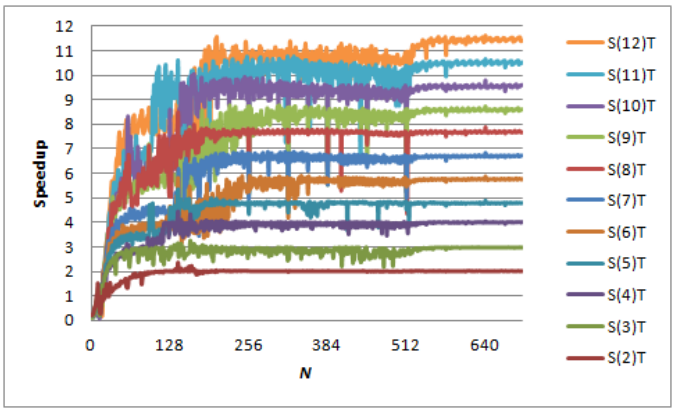

Fig. 5. Speedup in Traditional (T) Operating System

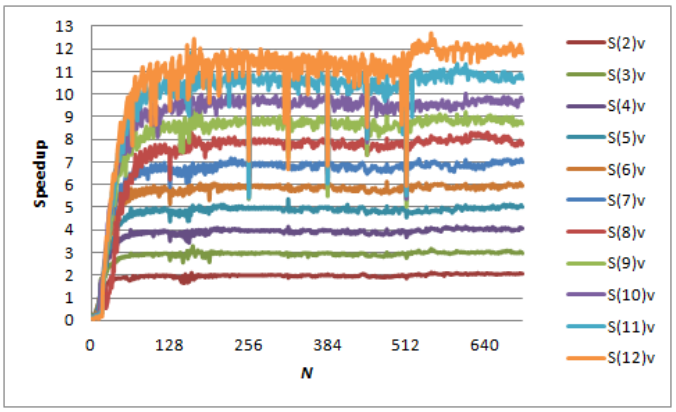

Fig. 7. Speedup in Virtualized (v) Operating System

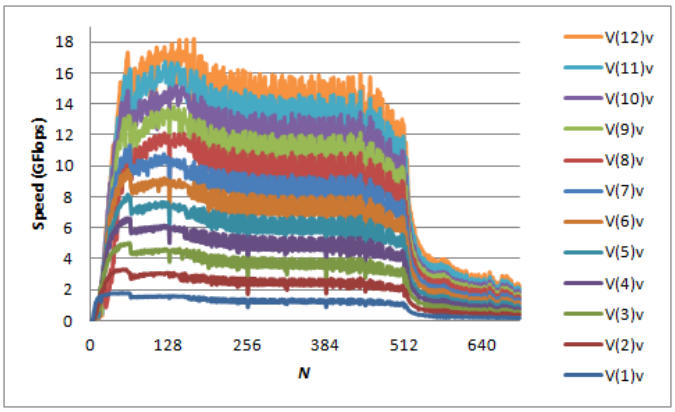

Fig. 6. Speed in Virtualized (v) Operating System

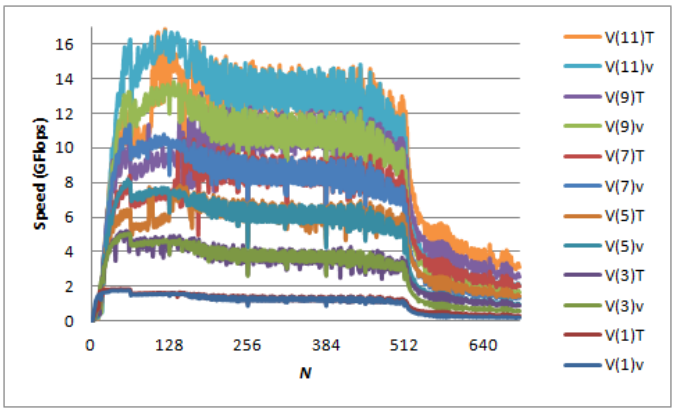

Fig. 8. Speed comparison for odd processing elements

Figure 5 depicts the speedup as a function of matrix size N for each test case with different number of processing elements $P = 1, 2, \cdots, 12$. The speedup curves satisfy Gustafson's Law [12] and saturate below maximum speedup P besides the speed degradation in L4 region.

V. Parallel Matrix Multiplication in Virtual Environment

This Section presents the result of the baseline experiments in virtual environment. The speed graph expressed in gigaflops versus matrix size N is shown in Figure 6 for $P = 1, 2, \cdots, 12$ processing elements. Figure 6 also presents huge performance degradation when $N > 512$ similar to the traditional environment.

Figure 7 depicts the speedup as a function of matrix size N for $P = 1, 2, \cdots, 12$ processing elements. The difference in this environment is the existence of a superlinear L4 region, which is emphasized for $P > 6$. This happens due to existence of a superlinear region when using the second L3 cache compared to the experiments performed only on one chip with one L3 cache.

VI. Traditional vs Virtual Environment

This Section compares the performance of traditional and virtual environments using the performance baseline presented in Sections IV and V.

A. Speed Comparison

Comparing Figures 4 and 6 one can conclude that the curves are nearly identical. All L1, L2, L3 and L4 regions defined in [6] are expressed in the same range of N for particular P. But, there is a difference for speed values in different regions. Figures 8 and 9 correspondingly present the speed difference between traditional and virtual environment for odd and even number of processing elements P.

The figures present that the virtual environment performs with discrepancies. On contrary to our hypothesis, virtual environment provides better performance in L1 and L2 regions compared to traditional as number of processors P increases. In L3 region both environments provide similar performance. But virtual environment provides huge performance drawback in L4 region compared to traditional depicted in Figure 10.

B. Speedup Comparison

Speedup comparison is depicted in Figures 11 and 12. On contrary to our hypothesis, one can conclude from both figures that speedup in virtual environment is greater than speedup in traditional environment.

The performance drawback in virtual environment compared to traditional is exposed in the L4 region. Figures 13 and

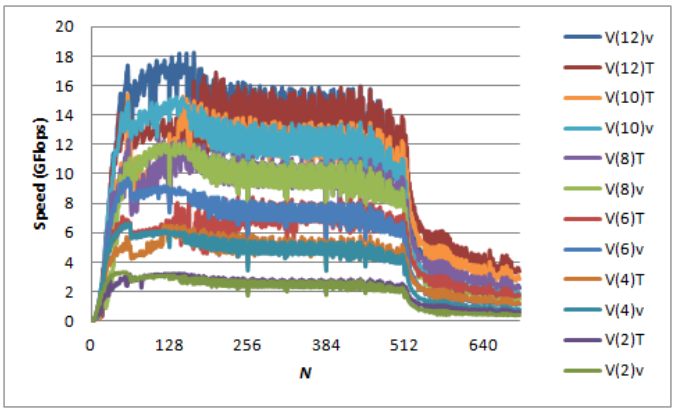

Fig. 9. Speed comparison for even processing elements

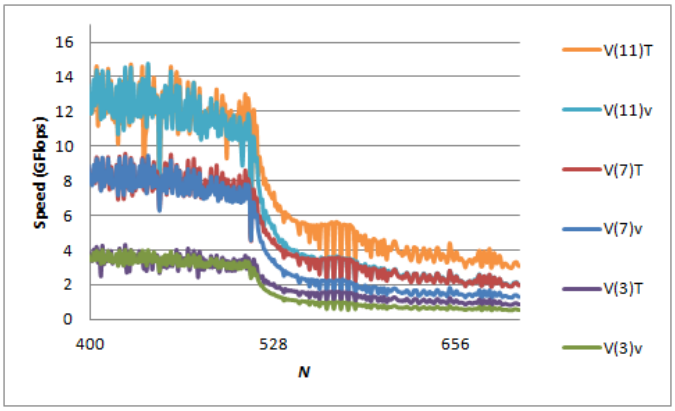

Fig. 10. Speed comparison in L4 region for better presentation

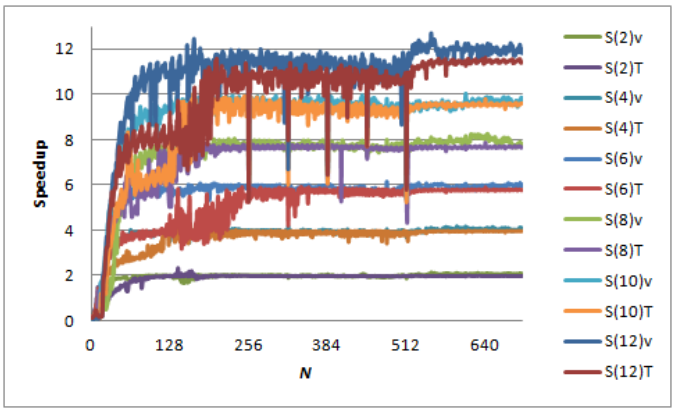

Fig. 12. Speedup comparison for even processing elements

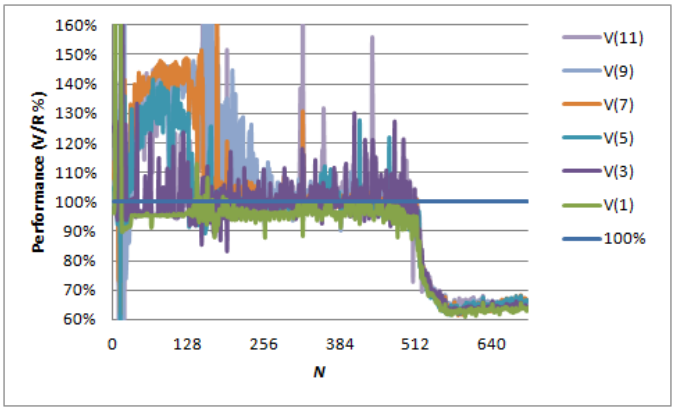

Fig. 13. Relative Performance for odd processing elements

14 present the relative performance expressed as percentage via ratio of achieved speeds in virtual and traditional environments for odd and even number of processing elements P. It is assumed that the speed in traditional environment is 100%.

Using any processors P from 3 to 12, the virtual environment provides better performance than traditional in L1, L2 and L3 regions. For L4 region, there is a huge performance drawback in virtual environment compared to traditional, despite the performance drawback in both solutions in this region, compared to regions L1, L2 and L3.

C. Performance Comparison in Cache Regions

Table I presents the average performance ratio between virtual and traditional environment for regions L1, L2 and L3 as a group where virtual environment provides better performance, as well as for L4 region where virtual environment

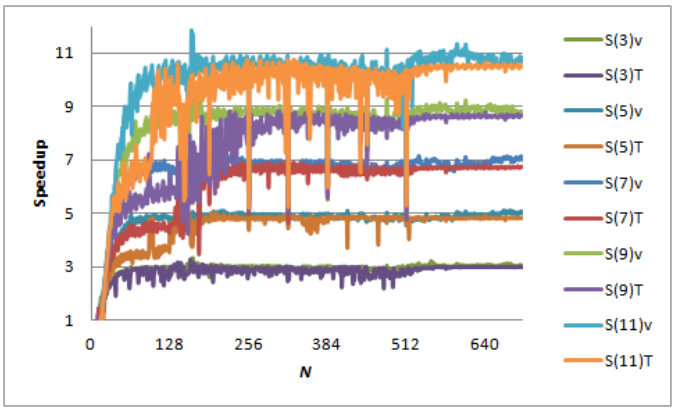

Fig. 11. Speedup comparison for odd processing elements

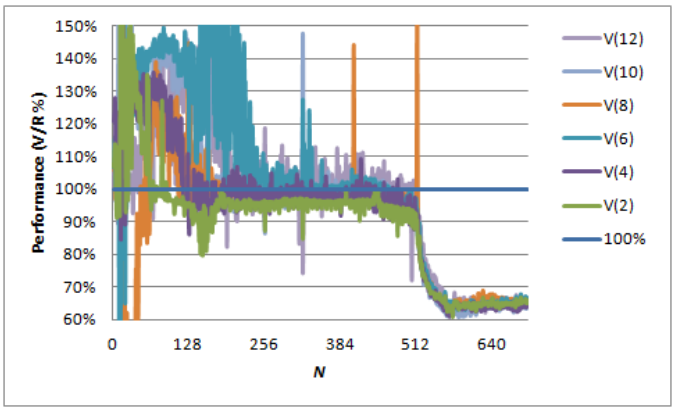

Fig. 14. Relative Performance for even processing elements

P	L1-L3 Regions	L4 Region
1	98.02%	64.88%
2	99.72%	66.51%
3	101.54%	66.27%
4	104.29%	65.79%
5	105.62%	66.42%
6	114.62%	67.07%
7	110.00%	66.79%
8	98.26%	67.82%
9	111.42%	66.75%
10	109.30%	65.28%
11	105.80%	67.14%
12	109.23%	68.26%
Avg	**105.65%**	**66.58%**

TABLE I
VIRTUAL VS TRADITIONAL AVERAGE SPEED PERFORMANCE

provides huge performance drawback compared to traditional. All performance percentages are given for each processing element P from 1 to 12.

The maximum performance as shown in Table I for virtual environment is 14.62% better than traditional in L1-L3 region. The results show average 5.65% better performance than traditional before L4 region, but only 66.58% of performance that the traditional environment provides in L4 region. It also means that in this region the performance is 33.42% worse than traditional.

VII. Discussion

The experimental results seem very discrepant. Our hypothesis that programs will run slower in virtual environment compared to traditional server failed in many test cases. The similar situation is also shown for speedup when executing in parallel.

Figures 13 and 14 present that for each number i of processing elements ($i = 2, 3, ..., P-1$) virtualization provides better performance than traditional in L1 and L2 regions. One can conclude that virtualization handles better in distributed environment rather than shared memory.

As additional confirmation to conclusion, L3 cache is "semi-shared semi-distributed", i.e. it is shared but not for all data. In L3 region virtualization and traditional environment provide similar performance.

The huge performance drawback in L4 region that virtual environment provides can be explained due to sharing the last level cache - shared memory, despite both test environment create evenly number of cache misses.

VIII. Conclusion and Future Work

Virtualization becomes necessity as technology for modern datacenters. It introduces additional layer in overall model which not always provides performance drawbacks.

We performed detailed experiments and concluded a huge performance discrepancy in virtualized environment.

Virtualization provides almost equal performance of 98% as traditional for sequential execution on computationally and memory intensive matrix multiplication algorithm. Using parallelization it provides even greater speed of almost 15% for particular number of processing elements in L1 and L2 regions.

The virtualization loses the battle in L4 region when a lot of costly cache misses appear. Its performance is 33.42% worse than traditional in this region.

Despite the hypothesis, in this paper the experimental results prove that virtualization performance is even better than traditional for distributed memory, rather than shared where there is a huge performance drawback.

In this paper we use only one active virtual machine working with all physical machine resources. We plan to extend our efforts to define a model to determine the best resource allocation among several active virtual machines to achieve maximum performance. Another imperative is virtualization performance in cloud computing.

***Abstract*— Replicated execution of distributed programs provides a means of masking hardware or software failures in a distributed system. Application level entities (processes, objects) are replicated to execute on distinct processors. Such replica entities communicate via message-passing. Non-determinism within the replicas could cause messages to be processed in non-identical order, producing a divergence of state. The replicas could thereafter produce inconsistent responses to identical messages and hence appear to be faulty. The partial-order model of distributed computations based on the happened-before relation like primary-backup approach has been criticized for allowing false causality between messages, the false causality causes unnecessary blocking processes and results in high time overhead for replicating entities. In this paper we use the concept of causal memories and multi version states to reduce the false causality between messages. We capture the read/write operations on the variables of each process to find out the dependencies between messages, and save some old values of variables to use in cases the read that operations may cause divergence in the states of replicas. The results of simulation show that this approach has lower execution time than the primary-backup approach.**

***Keywords*— Causal Memory, Replicated Distributed Systems ,Replication Consistency**

I. INTRODUCTION

Active replication is a well-known technique for achieving fault-tolerance. Such a technique is particularly attractive in a distributed system, where replicate execution on processors with independent failure modes can be used for masking failures. Duplex system [1] is an architecture for fault tolerance that consists of two processes that are developed using design diversity techniques [2] called *versions*. Versions perform the same task by communicating with a *coordinator*, which discovers possible failures. Unchecked, non-determinism within the replicas could lead to a divergence of state. The replicas could thereafter produce inconsistent responses to identical messages and hence appear to be faulty. This paper seeks to identify possible sources of non-determinism replicated systems and proposes a well-defined generic mechanism via which consistency may be maintained [3].

Most practical distributed programs employ a variety of mechanisms for controlling interactions between processes (e.g. timeouts, prioritized messages), which are potential sources of non-determinism; but these are not incorporated in the basic state machine model of active replication considered in the literature[4]. We therefore propose a more expressive, enhanced, concurrent processing model based on processes (or objects) interacting via messages and then show how such processes may be replicated. As in the replicated state machine model, we assume that tolerance to a wide range of processor failures (Byzantine [5] in the worst case) is required.

A fundamental problem in distributed systems is that of predicate detection detecting whether a global condition occurs while running a distributed program. Its main application is in the testing, debugging and monitoring of distributed programs. Predicate detection is usually specified in a model of distributed computation based on a happened-before relation [6][7] like primary-backup approach, which models the independence of concurrent messages on different processes. However, it has been criticized for allowing false causality between messages [8]. In the primary-backup strategy [4], one of the replicas, called the primary, plays a special role: it receives the invocations from the client process, and sends the response back. Given an object x, its primary replica is noted prim(x). The other replicas are called the backups. The backups interact with the primary, and do not interact directly with the client process.

Causal memory is based on Lamport's concept of potential causality [9]. Potential causality provides a natural ordering on messages in a distributed system in which processes communicate via message passing. We introduce a similar notion of causality based on reads and writes in a shared-memory environment. Causal memory requires that reads return values consistent with causally related reads and writes, and we say that "reads respect the order of causally related writes." Since causality orders messages only partially, reading processes may disagree on the relative ordering of concurrent writes. This provides independence between concurrent writers, which reduces consistency maintenance (synchronization) costs. The idea is that the synchronization required by a program is often specified explicitly and it is not necessary for the memory to provide additional synchronization guarantees.

II. PRELIMINARIES

A distributed system is considered as different processes $ap_1, \dots, ap_n$ such that they communicate to each other by message passing through FIFO and reliable channels with finite delay.

Each process ap_i has a memory that contains some variables noted by $\boldsymbol{\mathcal{M}_i} = \{m_1, m_2, \dots, m_l\}$ with initial value $\perp_i$ for each m_i. The behavior of a process ap_i is considered as a sequence of states $\boldsymbol{S_i} = \langle S_i^1, \dots, S_i^k \rangle$ such that each state consists of some values for the variables in the memory of the process noted as $S = \{x_1, \dots, x_l\}$. Each state transformation is written as $S \xrightarrow{o} S'$. Transformation $\xrightarrow{o}$ means that operation o is done[10]. We also have:

$$S \xrightarrow{o^1 o^2 \dots o^n} S' \Leftrightarrow S \xrightarrow{o^1} S \dots S \xrightarrow{o^n} S'$$

Possible operations that cause transformation from a state to another are listed below[11].

- *Writing a new value into a variable in the current state of a process.* Operation w_h stands for writing a new value into the variable m_h.
- *Reading value of a variable from the current state of a process*. Operation r_h stands for reading the current value of a variable m_h.
- *Sending message to another process.* Operation snd_i stands for sending a message to ap_i.
- *Receiving message form another process*. Operation rec_l stands for receiving a message from ap_l.
- *Waiting until receiving the next message.* This operation is written as $wait$.

III. FORMAL DESCREPTION OF CAUSALITY

A. Execution

Behavior of a process can be partitioned into a number of *executions*. A sequence of transformations is named an *execution* if it is in the form of $S \xrightarrow{rec_l o^1 o^2 \dots o^n wait} S'$, which means that it starts with receiving a message and finishes with waiting to receive the next message. The inner operations might be write, read, or send message operations. Thus, an execution can be written in a simpler way by the sequence of operations occurred in it in the form of $E = \langle rec_l, o^1, o^2, \dots, o^n, wait \rangle$. So the behavior of the process ap_i can be written by a sequence of executions in the form of $\boldsymbol{\mathcal{E}_i} = \langle E_i^1, \dots, E_i^k \rangle$.

B. Relations Between Operations

1) Happened Before Dependency

Lamport in [12] presents the concept of the happened-before relation. The happened-before relation $\prec_i^{hb}$ is a partial ordering such that $o \prec_i^{hb} o'$ if and only if the operation o in ap_i is done before the operation o' in ap_i.

2) Causal Dependency

The causality relation $\prec_i^{ca}$ is an ordering for two operations o and o' in a process ap_i, $o \prec_i^{ca} o'$ if and only if one of this conditions is held.

1.Both o and o' belong to the same execution and $o \prec_i^{hb} o'$.

2.o is a write operation on the variable m_j and o' is a read operation from m_j that executed after o (also named as read-from relation).

3.There is some o'' such that $o'' \prec_i^{ca} o'$ and $o \prec_i^{ca} o''$.

C. Relations Between messages

1) Mesaage Independence

For two executions $E_i^k = \langle rec_l, o^1, o^2, \dots, o^n, wait \rangle$ and $E_i^{k'} = \langle rec_{l'}, o'^1, o'^2, \dots, o'^{n'}, wait \rangle$ of a process ap_i, the independence relation $\bowtie$ between messages rec_l and $rec_{l'}$, is a reflective, symmetric and non-transitive relation that is defined as followed [13]:

$$rec_{l'} \bowtie rec_l \Leftrightarrow \nexists m_h \in \mathcal{M}_i: (w_h \in E_i^k \wedge r_h \in E_i^{k'}) \vee (r_h \in E_i^k \wedge w_h \in E_i^{k'}) \vee (w_h \in E_i^k \wedge w_h \in E_i^{k'})$$

In simple words, if two executions perform some operations such as write/read, read/write and write/write on some common variables, their input messages are not independence from each other. Thus changing the order of these two executions may result in different outputs. If two input messages are independent, then they are called *dependent*.

2) Input-Input Causal Dependency

For two execution $E_i^k = \langle rec_l, o'^1, o'^2, \dots, o'^n, wait \rangle$ and $E_i^{k'} = \langle rec_{l'}, o'^1, o'^2, \dots, o'^{n'}, wait \rangle$ of a process ap_i, the causal input-input dependency $\prec_i^{iica}$ is defined as followed:

$$rec_{l'} \prec_i^{iica} rec_l \Leftrightarrow rec_{l'} \prec_i^{hb} rec_l \wedge \exists m_h \in \mathcal{M}_i | (r_h \in E_i^k \wedge w_h \in E_i^{k'}) \wedge \left(\exists rec_{l''} \in E_i^{k''} \middle| w_h \in E_i^{k''}\right) \Rightarrow rec_{l''} = rec_{l'} \vee rec_{l''} \prec_i^{hb} rec_{l'}$$

D. Version Consistency

Two running versions are consistent if the causal input-input relations in both of them are the same.

IV. PROPOSED ARCHITECTURE FOR VERSION CONSISTENCY

A duplex system consists of one coordinator and two versions. To achieve version consistency, it is necessary that two versions that are executing identical received messages follow the same input-input dependency relations. For this purpose, the version that processes a received message for the first time through coordinator, dictates the causal input-input dependency relations for the other version. Therefore, it sends this dependency information to the coordinator after its received message processing gets completed.

Versions are divided into two isolated groups that send and receive message from only from versions in their own group.

When the coordinator receives a message that has been already processed in another version, it uses its already obtained dependency information to decide whether to send the message or postpone it.

On the other hand, the versions use multi-version approach; they keep the log of write operations performed by all executions. When a version receives a message that its causal input-input dependency relations have been dictated by the other version, it uses this log to perform read operations such that the two versions are kept consistent.

Example 1: Consider two process versions ap and ap' with memory $\mathcal{M} = \{m_1, m, m\}$ and $\mathcal{M}' = \{m'_1, m'_2\}$ respectively (the memory of the two versions are assumed different due to design diversity approach). Coordinator receives a message l with ap as its target. Coordinator finds

that the message l with target ap' has not been received before, therefore it sends l to ap. The version ap performs operation $w_1(1)$. Next, a similar case happens for message m with target ap, and performs $w_2(0)$. It is clear that $l \bowtie m$, so the coordinator after processing m does not declare any dependency between m and l. Next, coordinator receives message m that has ap' as its target, the coordinator finds that m has been processed in ap but there is no message that has dependency with m that has not processed in ap' yet. Although the message l in ap has been processed before m, but it is not necessary for ap' to wait for this message. Thus, the coordinator sends m to the ap'. ap' executes m and performs $w_1(0)$. Next, coordinator receives message n that has ap as its target and sends it to ap. ap performs $r_1(1)$, the variable that has previously been written by the message l. This makes l and m dependent. Thus, ap after executing n informs the coordinator and notes l as a prerequisite for n. After this, coordinator receives message n that has ap' as its target. Coordinator finds that the prerequisite l has not been processed in ap' before, thus it postpones n until l is received and processed by ap'.

Example 2: Consider ap and ap' as they are defined in the previous example. Version ap receives and processes messages l and q that perform operations $w_0(1)$ and $r_0(1)$ respectively. Thus, the ap informs coordinator that q is causally dependent to l. Version ap' receives and processes messages l and n that perform operations $w_1(1)$ and $w_1(2)$ respectively. Note that ap' has saved the log of write operations, therefore it knows that the current value of m_1 is 2 and the value that l has written on it is 0. Now the coordinator receives the message q which has ap' as target. Coordinator finds that q depends on l and also l has already processed in ap'. Thus, the coordinator sends q to ap' and piggybacks its dependency information. q wants to perform a read operation on m_1. ap' finds that q depends on l, so it must return the last value of a write operation on m_1 which has been performed performed by l, so as a result 1 is returned and the operation $r_1(1)$ is performed.

The details of the process of the coordinator and the versions are described below.

A. Coordinator Process

The coordinator process is responsible for the consistency between running versions. To achieve this, each process in order to receive next message, sends a request message to the coordinator, and the coordinator sends the first available message to the process. After processing the received message, the process sends the dependency information to the coordinator. The coordinator is responsible for coordinating the input messages and must forward the messages for the process versions such that the causal consistency between processes is guaranteed. To achieve this, the coordinator needs to save the dependency information for each version.

1) Data Structures

The required data structures for the coordinator process are listed below:

- *Message (msg):* consists of the sender identifier, message identifier (id), a boolean that determines whether the message has been processed before in the other version or not (*first_exec*), the list of message identifiers which this mrssage depends on them (*dep*), the timestamp (*ts)* and the message content.
- *Message Causal input-input dependency information*: dep_k^{id} consists the set of input message identifiers that have causal input-input dependency relation with message with identifier id that has been processed by k[th] version.
- *Messages Executing Now (exec_now)*: $exec_now_k$ contains identifier of the message which is executing in the kth version at the current time.
- *Different Order Messages (dif):* dif_k contains the message identifiers, which have been executed only in the kth version.
- *Message Queue(msg_queue):* msg_queue_k represents the message queue of the kth version.

2) Processing the request for next message

The coordinator fetches message from the message queue. Then it checks whether the fetched message has been executed in the other version than the one requesting. Three cases may occur:

Case 1: *The other version has not received this message yet.* In this case, the coordinator sends the message for the requester.

Case 2: *The other version has received the message and it is executing this process now.* In this case the coordinator checks whether the processed messages for both processes are identical or not. If yes, it sends the message for the target, else it postpones this message and fetches the next message from the queue.

Case 3: *The other version has received and executed the message completely*. In this case, the coordinator checks whether the message processed by the other version has dependency to a message that the requesting version has not received or not. If no, it sends the message, else it postpones it and fetches the next message from the queue.

Algorithm 1 shows the pseudocode of the these operations.

Algorithm 1:
Coordinator - Receiving a request for next message

```
Function Msg_req(version, last_msg)
/*last_msg is the dependency information of the last processed message*/
    if not last_msg.first_exec
        remove last_msg.id from dif_{1-version.number}
    else
        dep^{last_msg}_{version.number} ← last_msg.dep
    end if
    Select_next_message(version)
End Function

Function Select_next_message(version)
    selected ← false
    msg ← read first element of the msg_queue
    while not selected do
        if exec_now_{1-version.index} equals msg.id
            if dif_{1-version.number} equals dif_{version.number}
                msg.first_exec ← false
                Send(version,msg)
                selected ← true
            else
                /*postpone this message*/
            end if
        else if msg.id ∉ dif_{1-version.number}
            msg.first_exec ← true
```

```
            Send(version,msg)
            selected ← true
        else if dif_{version.number} ∩ dep^{msg.id}_{1−version.number} = ∅
            msg.first_exec ← false
            msg.dep ← dep^{msg}_{1−version.number}
            Send(version,msg)
        selected ← true
        else
            /*postpone this message*/
        end if
        if not selected
            msg ← read next element of the msg_queue
        end if
    end while
End Function
```

3) Sending message to the target process

When the above requirements for sending a message have been satisfied, the coordinator process sends the message to the target. If this message has been previously processed by the other version, the messages with causality dependency with the current message also must be sent to the target version. The pseudocode of this algorithm is given below.

Algorithm 2: Coordinator – Sending the next message

```
Function Send(version,msg)
    exec_now_{version.index} ← msg.id
    msg.ts ← clock
    Send msg to version
End Function
```

B. Versions

1) Data Structures

- *Variable History (H):* for each variable m_k in the state of a version, H_k keeps track of the values written in that variable by all the received messages.

2) Reading variable from the current state

Two cases are possible:

Case 1: *Input message has no bent previously processed by the other version (exec_first is true).* In this case, the process reads the last value written on the variable. The read operation results in causal dependency between the current message and the message that has previously written on this variable, therefore, it must be added to the list of dependency of the current message.

Case 2*: Input message has not been previously processed at the other version*. Since each version, has saved the messages received by the other version, it must read the last value that its writer message exists in the list of messages that has been executed by the other version (*msg.dep*).

The pseudocode of the read operation is described in algorithm 3:

Algorithm 3: Versions – Read operation

```
Function Read(m_k)
    If msg.first_exec
        add H_k.last_writer to msg.dep
        return H_k.get_value(H_k.last_writer)
    else if H_k.writers_set ∩ msg.dep = ∅
        return ⊥_k
    else
        last_writer ← element of writers_set ∩ msg.dep with
      highest value for ts
        return H_k.get_value(last_writer)
    end if
End Function
```

3) Writing new values into a variable of the current state

The new value of the variable and the identifier of the current processing message are added to the history of the variable.

The pseudocode of the write operation is described in algorithm 4:

Algorithm 4: Versions – Write operation

```
Function Write(m_k,v)
    if msg.first_exec
        add H_k.last_writer to msg.dep
        add (msg,value) to H_k
    end if
End Function
```

4) Sending Message To Other Processes

In order to send messages to other processes o, the process sends the message content along with its identifier to the target process. It also sends a request to the coordinator to receive the next message. It also sends the identifier of the processed message to the coordinator. If the current executing message has not been processed by the other version (*first_exec* is false), the messages that are causally dependent to it are piggybacked to the message and are sent to the coordinator.

V. GARBAGE COLLECTION

Saving complete history of a variable, results in high storage overhead for the versions, thus it is necessary to remove the unused data. To achieve this, the *masked message* is defined. A masked message is a message no current value of any of versions' variables has been written by this message, and also none of the messages in the "different order messages (*dif*)" data structure are causally dependent to it. When due to the execution of new messages, the direct impact of old messages on the current state of the system becomes completely masked, it means that the next messages are not in the causal relation with the old messages, so the values written by them may be removed from the variable histories.

VI. PERFORMANCE EVALUATION

The method based on causal memories and multi version states need to save multiple values for each variable, thus it uses additional amount of memory to keep the state of the processes. But it reduces the waiting processes and improves the performance of the whole system.

A simulation is developed using SimJava 2 Tool and the execution time of a replicated distributed process using primary-backup and causal memory techniques are compared. There are 6 pairs of processes that communicate via message passing, each pair of processes are developed using N-Version Programming approach and they perform identical executions on the same input. The process and communication delays are generated using exponential distribution with mean value 200 time units for communication delays and 50 time units for delay of processing each input message. Each test is started by a number of initial requests (3, 6, 12, 30 and 60) and each request is assumed to be processed by 500 steps in different

processes, and after each step, the request is sent to another process to continue execution. The testes are performed under different conditions about the probability of causal dependency between input messages (for causal memory approach). The right most column of the chart shows the execution time of this test using primary-backup approach. The results in figure 1 show that increasing the probability of causal dependency between messages, increases the execution time of all requests. In most cases the causal memory approach has lower execution time than the primary-backup approach.

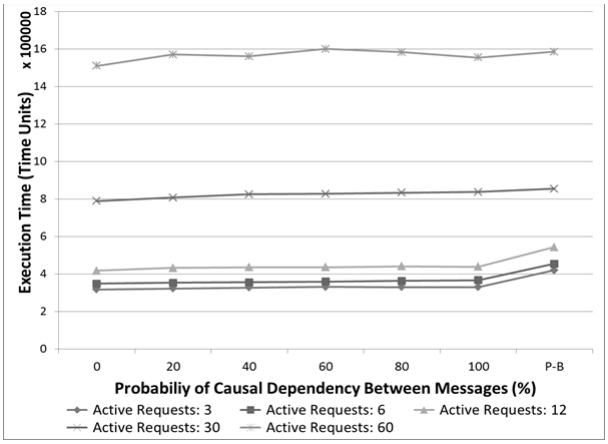

Figure 1. Execution time of replicated Systems using primary back-up model and causal memory model with different dependency probabilities

VII. CONCLUSION

In this paper, we used the idea of causal memory and multi version states to reduce the overhead of existing methods of divergence avoidance in duplex systems. These existing methods are based on Lamport happened-before rule and results in false causality and unnecessary blocking process. In the case of variant processing times for identical messages in different versions, or variant delays communication networks, generation of replies may occur in different orders, and using methods based on happened-before causality relations results in high overhead. By using causal memory approach instead of primary-backup, these unnecessary waiting for processes can be removed and the performance of replicated programs can be improved.

An improved approach to track forest fires and to predict the spread direction with WSNs using mobile agents

Ivan Vukasinovic*, Goran Rakocevic**
School of Electrical Engineering, University of Belgrade
ivanvuk88etf@gmail.com

Tracking of fires in large areas of land/forests can be done by using Wireless Sensor Networks (WSNs) embedded into those areas. Mobile Agents (MAs) injected into the WSNs can help about fire detection and can maintain the information about the perimeter surrounding the fire. This paper proposes a further improvement of the state-of-the-art in the manner of predicting the direction in which the fire might spread. The proposed solution uses land humidity sensors and MAs that are sent on the edge of the perimeter formerly created to gather humidity data and to make a prediction based on the gathered data. The prediction is sent to the appropriate fire department unit enabling them to react quickly.

I. INTRODUCTION

Forests cover vast areas, so preserving them is vital to our eco-system. Fires that occur in forests are an immediate danger leaving desolation and destroying our „oxygen generators“. That is why it is important to contain fires and effectively extinguish them. A Forest Fire is modeled as a chain of three links: fuel, oxygen and a heat source. So containing a fire means decreasing the amount of these three links. Extinguishing can be done by breaking the chain, meaning one of the three is taken out of the equation.

Wireless Sensor Networks consist of a large number of independent nodes that can sense the environment around them as well as process the sensed data. They are cheap, easy to set up and can provide certain information needed by measuring them. Such information is:

- temperature
- Land/tree humidity.

Mobile Agents are a form of intelligent, mobile processes that can migrate between the devices in a network and execute the given task. They are effectively used to process data in a distributed fashion, so that no junk data is transmitted over the network. In this manner energy is saved by transmitting only needed data, which is important in networks with energy constraints such as Wireless Sensor Networks.

So deploying Wireless Sensor Networks to sense data about the environment in real-time inside the forest and using Mobile Agents to process data in most energy effective way sounds salient.

II. PROBLEM STATEMENT

Forest Fires according to the [2] can spread quickly so predicting the direction in which they are going to spread is very important. This can be achieved by monitoring the three links in the fire chain mentioned in the introduction section. Monitoring heat sources is done by measuring the temperature with temperature sensors in the WSN nodes deployed in the forest. Fuel is monitored by knowing the kind of growth, its humidity and quantity, as fuel moisture is very important for fire prediction said in [3]. Oxygen can also be monitored by taking weather forecasts, especially wind speed for the geographic area in which the forest resides. But weather conditions can change quickly in small areas therefore we need a real-time values for previously mentioned measurement. Weather forecasts are also to be taken into considerations as mentioned in [3], [4]. But in order for the prediction to be most effective it not only has to be precise it also must be delivered in fastest time possible to the appropriate people, firefighters, rangers, etc...

Unfortunately as mentioned in referenced papers forest fires will become more and more troublesome because of various climate trends so containing and extinguishing them is important since we need our “Oxygen generators”!

III. PREVIOUS WORK

Mathematical models for simulation and predictions have been devised in research papers [5]. Similar work is done by [1] which proposes deploying WSNs inside the forests and when fire is detected then sending the MAs to form a perimeter around the fire and provide fire fighters with appropriate data about the perimeter. Our approach is an improvement of this scheme in a manner that fire spread prediction is added. So when Firefighters and their resources are scarce and they cannot cover the whole perimeter they must choose where to go first on the perimeter. Our solution provides them an estimate about the direction in which the fire will spread so that they go there first in order to maintain the perimeter around the fire more effectively.

IV. PROPOSED SOLUTION

We divided the idea into the four following sections for easier reading.

A. Environment Scenario

Conditions needed for the proposed solution:

- Wireless Sensor Network nodes have already been deployed throughout the forest on trees and on the ground.
- Nodes have temperature and humidity sensing capabilities.
- Nodes support mobile agents by integrating one of the mobile agent platforms and have to be able to support multiple MAs on a single node.
- Each node has a Mobile Agent running on it.

B. Fire detection and perimeter forming

Mobile Agent running on each node is sensing the environment temperature so when a temperature threshold is detected fire is present. When this happens a perimeter surrounding the fire has to be formed. When the MA that detects the presence of the fire based on the temperature threshold it replicates itself and migrates to the neighboring nodes to form a perimeter alongside it replicated brothers, this is shown in Figure 1.

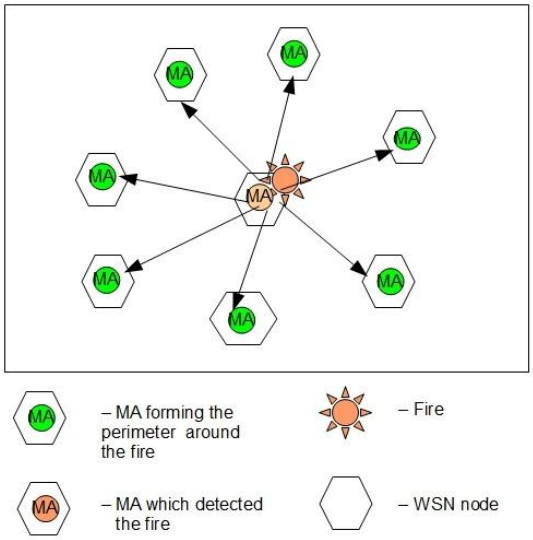

Figure 1: MA replicas forming the perimeter around the fire

Perimeter forming is done in the following manner: An MA first contacts the neighboring node to check if the neighbor node itself has detected the fire, if not it migrates to it and exchange the data with the residing nodes MA after which it deletes it and continues running as a perimeter MA. If the neighbor node MA has detected the fire the MA doesn't migrate to it, just gets its ID and timestamp of fire detection. This mechanism prevents duplicating the MAs on a node that already detected the fire and also allows the perimeter to grow as the fire expands which is shown in figure 2. First part of data needed for routing of MA replicas is the ID of the origin MA who made it, allowing tracking of which replica belongs to which original MA. Second part is data from the origin MAs which has the replica number of his older brother replicas. So the higher number the younger the MA is. Third part is the timestamp, to help find the first MA that detected the fire. This is needed when forming a Scout MA explained later in *Humidity data gathering*. So using timestamps, origin IDs and replica age, MAs forming the perimeter info is known.

C. Humidity data gathering

After the perimeter is formed a single MA referred to as the Scout is sent to visit each node in the perimeter and gather humidity and temperature data acquired by the nodes. A Scout MA is created by the youngest MA of all replicas of the origin MA. In case that only one origin MA exists there will be only one youngest MA who has the info about his older brothers residing nodes and it is easy for him to migrate from a perimeter node to a perimeter node and gather the data shown in figure 3.

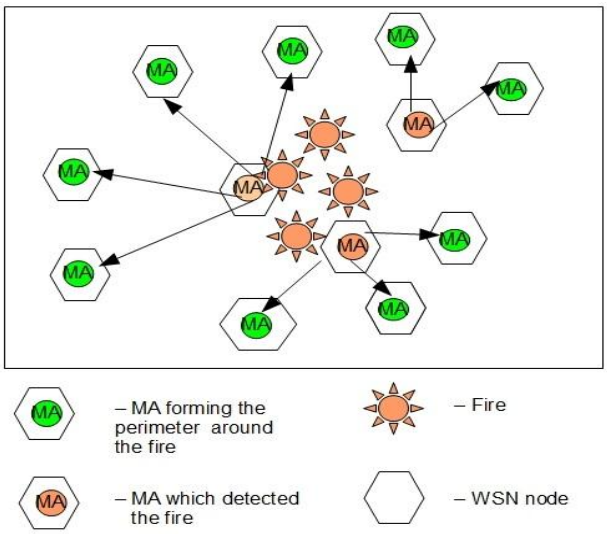

Figure 2: Fire perimeter expanding as the fire grows

The other case is that more than one origin point exists. In such each replica MA then consults its data for the ID and timestamp of other origins and its brother so that the youngest son of the youngest origin creates the Scout MA which is assigned to gather data, because it has all the info needed for routing about his predecessors.

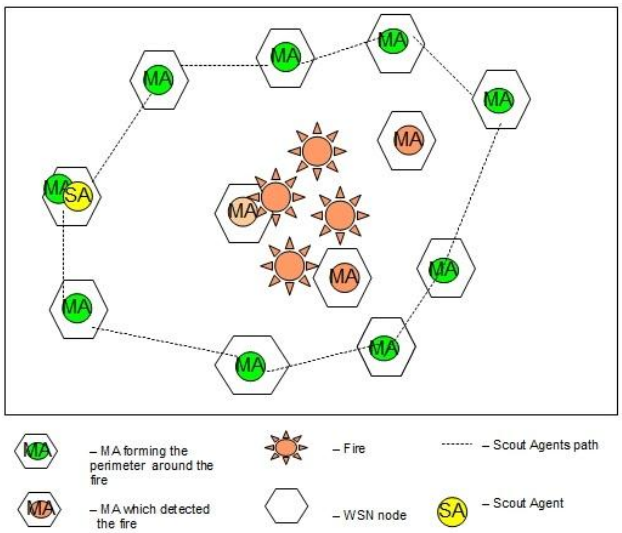

Figure 3: Data gathering by the Scout MA

D. Spread Prediction

After the scout gathers all the data then the data is processed on the last node the Scout MA visited. After the processing not only the perimeter info but the spread direction, which is calculated based on the equations in [5],[6]. Heat of pre-ignition is the main criterion for predicting the direction in which the fire will spread. It is calculated according to the equation from [5] shown here:

$$Q_{ig} = 250 + 1,116\, M_f,\ B.t.u./lb. \qquad (12)$$

In this equation only variable needed is M_f(fuel moisture) which we gather from the WSN nodes. The minimum value calculated out of all the nodes is the most probable direction in which the fire will spread.

This information will be provided to the appropriate authority, firefighters by sending the Scout MA with prediction information to them. In case that the computations are energy consuming they can be done on the device/computer to which the MA migrates when he goes to inform the firefighters...

V. SUMMARY

The improvement presented in this paper is introducing real-time humidity information in order to provide more accurate spread direction prediction based on that information. Further improvement could be to process the data in a computing center rather than in the WSN and also integrating the weather forecast for wind speed info. Some thought could be given into improving the equation with other parameters.

Abstract—
The EDGI project builds a federation of Desktop Grid sites, which provide volunteer and institutional compute resources. EDGI offers these resources to gLite, ARC, and UNICORE user communities. The jobs can be directly bridged to the Desktop Grids via the standard gLite, ARC, or UNICORE interfaces. The paper focuses on the UNICORE side, especially on the monitoring aspect. A bridging mechanism has been implemented in a modified UNICORE computing element to forward jobs towards the Desktop Grid servers. This component is part of the EDGI infrastructure, where all the bridge-related components and resources are continuously monitored by a central monitoring system. The monitoring system provides information about the traffic among the sites in the infrastructure. The paper gives a short overview of the EDGI infrastructure, especially the monitoring system and introduces the technical details about how the monitoring is integrated and supported by the modified UNICORE computing element. The introduced solution is part of the EMI software stack to make it easily accessible for UNICORE infrastructure providers.

I. Introduction

The European Grid Infrastructure (EGI) creates and provides an eScience infrastructure for European research communities. Those communities, reaching from high energy physics to humanities, can choose from different grid technologies to execute their computations: Grids of cluster computers, like the German D-Grid, supercomputers, like the Distributed European Infrastructure for Supercomputing Applications (DEISA), or desktop grids consolidated in the International Desktop Grid Federation (IDGF). Each of the technologies has different properties concerning access limitations, amount and types of available resources, and privacy properties. UNICORE [1] supports both clusters and supercomputers, which are also known as service grids (SGs). Extending UNICORE to support desktop grids (DGs) is the final step to enable UNICORE to operate with all available grid resources. This extension enables European eScience communities, especially UNICORE VOs, to access all available grid resources from one middleware.

Desktop grids collect idle resources from loosely coupled desktop computers. Each DG client only has to install a small client software to run computations. DGs exploit that compute capacities of modern computers are rarely exhausted while performing daily tasks, like reading mails and websites or writing texts. The DG client software now allows the utilization of idle capacities for scientific computations. The desktop computers form either an institutional/private/campus or a voluntary/public desktop grid. The first scenario aggregates idle resources out of computer pools of an university or out of employees' computers of a company. The second scenario motivates the general public to install DG client software on their home computers and therewith to donate compute resources for science similar to popular projects like SETI@home [2].

Since there is no high-speed network between the desktop computers, only a subset of applications is applicable to them, like parameter studies (PS). Parallel applications requiring a high-speed interconnect should still be executed on service grids. However, PS currently running on service grids can be outsourced to DGs, leaving more available resources for researchers in need of highly interconnected nodes. The power of the DG is the potential to collect and utilize millions of desktop computers owned by citizens. A public desktop grid can collect hundreds of thousands or even millions of computers from the volunteers worldwide, depending on how appealing the supported applications are for the citizens. In case of a campus desktop grid, the typical size is several thousands since they are collected within an institute/company.

The aim of the European Desktop Grid Initiative (EDGI) is to deploy desktop grid and cloud services for EGI user communities that are heavy users of distributed computing infrastructures (DCIs) and require an extremely large multinational e-infrastructure. In order to achieve this goal, software components of ARC, gLite, UNICORE, BOINC, XWHEP, ATTICS, and 3G Bridge have been integrated into a platform, which can move jobs from service grids to desktop grids. Therefore, EDGI extends ARC, gLite, and UNICORE grids with gateways to volunteer and institutional DG systems. EDGI also integrates a bridge between service grids and Eucalyptus, OpenStack, and OpenNebula cloud environments to be able to support QoS for the DG environments. This enables EDGI to explore new provisioning models in order to ensure a harmonized transition from service grids to desktop grids. EDGI will also provide a workflow-oriented science gateway to enable user communities to access the EDGI infrastructure more easily. The EDGI project established the IDGF

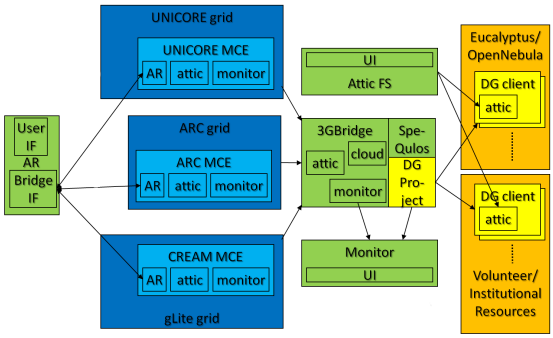

Fig. 1. The EDGI software infrastructure.

organization to coordinate DG-related activities in Europe, both for solving technical issues as well as to attract volunteer DG resource donors by disseminating results of the EDGI and EGI projects. IDGF and EDGI collaborate with EGI, EMI, NorduGrid, the UNICORE Forum, and interested NGIs.

The rest of the paper is organized as follows. Section 2 gives a short overview of the EDGI infrastructure. Section 3 describes the technical challenges of extending UNICORE as a UNiform Interface to Computing REsources to support multiple DGs. Section 4 describes the EDGI monitoring infrastructure. Finally, Section 5 concludes the work described in this paper.

II. Overview of the EDGI infrastructure

EDGI is a project supported by the FP7 Capacities Programme. This section will give a short overview of the key components of the EDGI infrastructure [3], which are developed and maintained in the project. The aim of the infrastructure shown in Figure 1 is to provide a gateway to desktop grid resources for those users who are familiar with gLite, ARC, or UNICORE type service grids and do not intend to move their environment to another type of grid. Adding a huge number of desktop grid resources can significantly increase the overall capacity of a service grid system.

Desktop grid systems can be built based on institutional or volunteer resources. In the former case, an institution (e.g., a university) is maintaining the resources, while in the latter case, the resources are provided by private PC owners. In DG systems, applications must be ported (i.e., modified according to the requirements of a DG software like BOINC) and validated (to make sure they do not cause any harm on the resource) before being deployed on the server. After the deployment, which includes registering the application with all of its binaries, work units can be submitted. In DG systems, volunteers trust the applications provided by the attached DG when letting the application run on their PCs. To store the validated applications centrally, a new *Application Repository* (denoted "AR" in Figure 1) has been introduced. The most important information related to an application are a detailed description, binaries, example input files, supported service grids and desktop grids. Users can also select an application and submit it to a well-known service grid.

The specially prepared *Modified Computing Element* (MCE inside gLite, ARC, or UNICORE in Figure 1) is responsible for forwarding the job to a desktop grid. Before doing that, it checks whether the application originates from the AR (through the "Bridge IF") and then whether the application is supported (i.e., registered) on the target desktop grid. Access to a desktop grid is provided by the *Generic Grid-Grid bridge* (3G Bridge) [4] component (depicted in the middle of Figure 1) running on the server of the target desktop grid system. The 3G Bridge is responsible for inserting the job as a work unit into the desktop grid system (BOINC or XtremWeb), for keeping track of its progress, and for reporting the status and results back to the service grid computing element.

The EDGI infrastructure is also able to utilize cloud computing resources (shown in the upper-right corner of Figure 1) by instantiating virtual machines to speed up computation when actual resources are considered unable to provide enough capacity. The dynamic scheduling of cloud resources is part of the newly developed SpeQuloS [5] software, which resides on the DG server. The Attic P2P file system [6] is used to store huge input files for jobs executed many times to decrease the load on the desktop grid server. Monitoring [7] in EDGI collects information about service and desktop grid components and provides a web-based portal to inspect the utilization of the overall infrastructure.

III. Implementation

This section describes the extension of UNICORE to access desktop grid resources. After starting with a brief UNICORE description, the implementation is described and critical technical details are outlined (please see [8] for a more detailed description).

A. UNICORE Ecosystem

The following section describes the distributed architecture of UNICORE. UNICORE is divided into three layers: client, service, and system. Users and their applications can access UNICORE services via different client tools. The UNICORE services, associated with the service layer, are loosely coupled Java Web services. They have to be registered in at least one well-known *Service Registry*. The concrete resources, clusters, or storage systems are UNICORE's *target systems* and are part of the system layer. The services on top of these target systems provide a system independent UNiform Interface to (COmputing) REsources (UNICORE).

UNICORE/X is the core component of a UNICORE site. It hosts the webservices for job and storage management. The *Target System Service (TSS)* is created by a factory (TSF) and provides access to native resources. It uses the backend component, the eXtended Network Job Supervisor (XNJS), sometimes referred to as the job management and execution engine of UNICORE. For job submission a *Job Management Service* is created and provided. The *Job Management Service (JMS)* handles the control flow of a single job: submit, abort, pause, and monitor. To execute these requests the XNJS is used. The *Storage Management Service (SMS)* offers unified

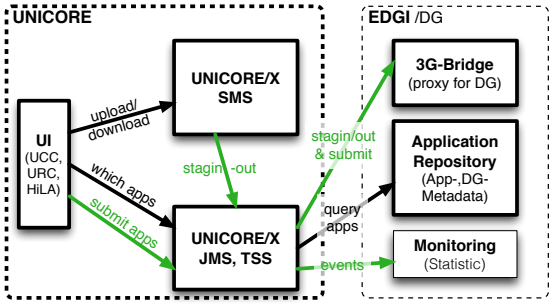

Fig. 2. Architecture and Interaction of UNICORE and EDGI components.

access to arbitrary storage systems. The main functionality is implemented inside the backend XNJS component. Finally, the *File Transfer Service (FTS)* enables concurrent file transfer operations.

These services are known as UNICORE atomic services (UAS) and are indirectly accessible through a *Gateway* that ensures security. Information about available services are stored in a special *Registry Service*.

The *Gateway* component is the single entry point to a UNICORE site. It authenticates all incoming requests and forwards them to their intended destination services. Replies are sent back to the clients. To authenticate users and assign roles to them, the Gateway queries the XUUDB, which is a user database mapping user credentials (certificates, distinguished names) to access privileges for each service and to a set of attributes, like Unix logins, roles, or projects.

The *Registry Service* provides a central point of registration for different services of a UNICORE installation. At least one registry is needed to run an installation.

The *eXtended Network Job Supervisor (XNJS)*, also called UNICORE engine, contains most of the core functionalities of a UNICORE site, which is used by most UASs. It uses the *Target System Interface (TSI)*, which enables a unified access to target systems for resource and storage handling. The XNJS handles the control flow of a job, the staging to and from local storage systems and submitting to local resource management systems. This is done through the TSI, which implements the access to native management and storage systems.

The Target System Interface (TSI) implements access to local systems. In a typical grid environment, a resource management software (RMS) schedules a job and a shared file system provides access to the working directory for the job. Currently, two types of TSI implementations exists: a java and a perl implementation. The java implementation is mainly used for test purposes. It executes a shell process and stores data locally. The perl implementation runs a set of perl scripts with different implementations for accessing Torque, SGE, OpenCCS, or PBS.

B. Architecture and Implementation

This section describes the changes required to enable DG job submission. Figure 2 shows UNICORE and EDGI components and their interactions. With the User Interface (UI), a user can upload his input data to an SMS, query a UNICORE/X server for available applications, and submit jobs using those applications and input data. The UNICORE/X server will download the input data from the SMS and submit the job to the 3G Bridge, which forwards the job to the target DG. After the job terminates on a DG client, the UNICORE/X server downloads the output data from the DG and stores it on the given target storage. Later, the user can download the results from the target UNICORE storage.

Typically, an UNICORE/X site represents a single cluster. The extension keeps this architecture by wrapping a single DG installation. Therewith, querying each UNICORE/X for application or resource information results in individual data for each DG. Additionally to submit a job, a user can choose a DG installation. Wrapping a target system is usually done by implementing a TSI. We decided to implement a java based TSI, which includes a full reimplementation of the TSI for accessing remote components like the application repository and the 3G Bridge.

The *staging process* is slightly different from a standard UNICORE system, because data has to be transferred additionally to and from the DG head node. The XNJS initiates through the TSI a stage-in process. This creates a working directory for the job and downloads every input file into this directory. In contrast to the stage-out process, this stage-in process is unchanged and works by using existing code supporting every UNICORE file transfer protocol.

Afterwards, the XNJS triggers a job submission and the new TSI transforms the UNICORE job request into a 3G Bridge request. This request cannot contain input data, which is probably hundreds of megabytes large. Thus, the 3G Bridge expects an alternative way to fetch the input data, e.g., via HTTP. The 3G Bridge is typically collocated with the DG management software on the DG head node, so the 3G Bridge moves these files to the correct place. To enable fetching input files, the filespace-directory, in which UNICORE creates working directories, is exposed via a HTTP-server. To inform the 3G Bridge about the download location, the input file location of the request is replaced by the corresponding remote URL.

If nothing unexpected happens, the status will change from PENDING to RUNNING and FINISHED. The new TSI observes this by polling the 3G Bridge. If FINISHED is reached, the 3G Bridge provides a list of output data with HTTP URLs. This data is downloaded to the job's working directory. This functionality is hooked in prior to UNICORE's normal stage-out process to enable a fully supported file transfer. Thus, the XNJS believes the computation is not finished until the output file has been downloaded from the remote HTTP server. After every file transfer is finished, the job and its files are deleted on the DG site, and the normal XNJS functionality continues: stage-out after job computation. This implementation preserves UNICORE/X stage functionality and supports different target and source storage systems. It also cleans the 3G Bridge or the DG head node up.

The *Incarnation Database (IDB)* is basically an xml-file

read by the XNJS. The IDB is used to describe native or local properties of the target system, for which the UASs provide an uniform interface. The IDB has roughly three parts describing the kind of local resources, CPU architecture, cluster size, the available applications, and specific execution environments used by applications, e.g., MPI. The solution updates the IDB at UNICORE/X start time with information from the application repository, which relates to the currently accessed DG. This can also be triggered from command line and can be continuously updated if an interval is specified. This eases the administrative effort, because newly available applications for DGs are automatically available for UNICORE users.

The *XMLLogReport* class handles the EDGI internal monitoring system (Section IV-E), but does not need to communicate with external components, because the monitoring system follows a pull model for observed nodes (Section IV-A). For this, a directory is exposed by an HTTP server. The `XMLLogReport` class writes monitoring events in files, handling the special XML format for the monitoring and cleaning up outdated files.

URL-passthrough is a concept realized in EDGI for glite to bypass local staging processes. Publicly available data can be downloaded directly from the DG clients. Otherwise, the data has to be downloaded to a UNICORE/X side, then to a DG head node, and from there DG clients could fetch them. This would result in a waste of bandwidth and potentially cause network bottlenecks on the UNICORE/X site or the DG head node. For bypassing, the URL has to stick to the following format: bypass://*[protocoll]*:///*[host,path to file]*:*[md5]*:*[size]*.

IV. Monitoring

A. Overview

The EDGI monitoring system provides information about EDGI resources, including historical and real time data of the connected grid systems. In particular, besides the UNICORE grids that we cover in this paper, monitoring must also integrate the following technologies: BOINC, XtremWeb, gLite, ARC and cloud technologies.

Figure 3 gives an overview of the components of the EDGI monitoring system. It depicts two sites as large rectangles: the central and a foreign site. The (single) central site is responsible for the following functions: 1) collecting, 2) storing and 3) displaying data. To collect data from (multiple) remote sites (1), the monitoring system uses "foreign probes". To centrally gather these data, it uses an additional probe at the central site. (2) Then, we store the data that goes through the probes in a local MySQL database and in a round-robin database (RRD)[1]. This latter database keeps data with different degrees of granularity depending on its age. For instance, it will keep all data of the last day, but it will use increasing levels of consolidation (thus loss) for weekly, monthly and yearly views. (3) To display data from the databases, we currently use a Java Server Faces web site run by a GlassFish[2] Application Server.

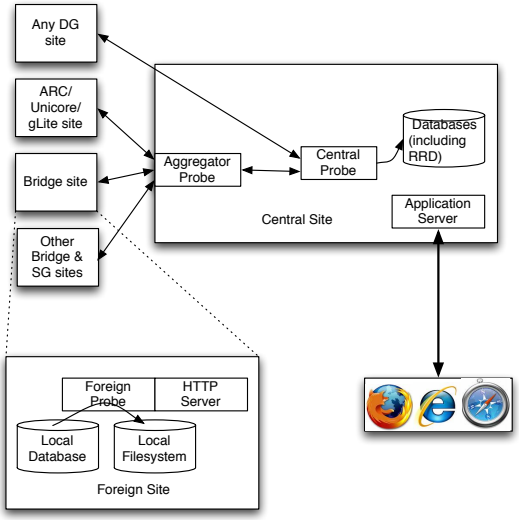

Fig. 3. Modules and components of the monitoring environment.

B. The Data

We get data from several different resources. In some cases, we need to query a BOINC or XtremWeb database, to get, for example, the number of available cores, the number of jobs that are running, or the number of FLOPs available. In this case, we just extract and filter the data into a different format: we periodically read from a MySQL database, write it in XML, for later storage in an RRD database. For other grids, we may have to produce data, based on job-related events, like job submission, completion, or failure, to know exactly what happened to each one of these jobs. This will enable us to compute the overall number of jobs that finished successfully or that failed, for instance. To have a better understanding of this latter case, we illustrate in Table I a number of events that two components of the EDGI infrastructure produce: the first one is the modified Computing Element, which submits jobs to the second one, the 3G Bridge, which finally submits jobs to BOINC or XtremWeb for execution. As we can see from the table, we can determine exactly what is happening to each job.

C. XML Creation

To make the data available, we use XML files. In practice, these serve as the glue that binds the monitoring system together. We publish the XML files on the resources sides and periodically download these files to the central site using the HTTP protocol. The advantage of HTTP is that it completely decouples communication between the foreign probes and the central probe. System administrators must configure their HTTP servers to enable the central probe to read the entire list of files available in the directory. The names of the XML files include the creation UNIX epoch. The central probe uses these timestamps to keep track of the files it has already read. It first reads the entire content of the directory, then determines which files are new, and, finally, it downloads them one by

TABLE I
EVENTS OF INTEREST IN EDGI

Event	Format

Submission	dt=2010-01-06_13:30:30 event=job_submission job_id=zzzzzzzzzz job_id_dg=yyyyyyyy output_grid_name=xw—boinc/xyz.com

one. For the sake of saving space, this scheme requires periodic cleaning of XML files on the local sites. System administrators can, e.g., use a cron daemon and file timestamps to regularly clean old files.

To provide an idea of how do these files look like, we give an example in Figure 4. This particular file contains events regarding job submission to a 3G Bridge, from an MCE. For convenience of the presentation, we split some job identifiers.

D. The Probe Concept

We run three sorts of probes: "foreign", "aggregator" and "central". The foreign probe runs in the monitored sites, such as BOINC, XtremWeb, 3G Bridge, etc.. The central probe is common to all monitoring data paths. It receives data like "80 cores" or "24 jobs" referring to some specific resource. The aggregator probe keeps track of data that is still changing across the different grids. For instance, if the 3G Bridge submitted a job to BOINC, we must keep its identifier to know when it finishes. The aggregator keeps track of the life cycle of jobs and sends consolidated data to the central probe using XML itself. In this example, when the job finishes, the aggregator probe can add one to the number of jobs that finished for that specific 3G Bridge, for that specific application, and output this fact in the next XML file it writes.

We offer two mechanisms to publish the XML data: one of them are "foreign probes", the other are Java and C libraries that developers can use in their source code. Usually these probes search for specific text patterns in log files or run SQL queries in databases to get data, e.g., job start, job finish, or number of CPU cores. If users want to read data from gLite resources, from BOINC, or from XtremWeb they should install the appropriate probes. For instance, in BOINC and XtremWeb, the main (but not single) goal of the probe is to collect data regarding the desktop grid alone, e.g., the number of running jobs, or the number of available CPU cores. In the 3G Bridge, the metrics are slightly different, as we want data regarding jobs that cross the bridge. Overall, we have the probes for BOINC and XtremWeb, the gLite modified Computing Element (MCE) probe, the 3G Bridge probe, the aggregator probe and the central probe. The probes have been developed in Java. Some of them work as stand-alone daemons, while others run under the control of a cron daemon. This means that a system administrator must manually control the former, while the latter reads a number of metrics and sleeps until the end of the next period. Table II enumerates which probes are daemons and which ones are not.

MCE/gLite	Cron
3G Bridge	Cron
Aggregator	Daemon
Central Probe	Daemon

E. XML Libraries

Although the monitoring probes still run in an important fraction of the EDGI infrastructure, they have important disadvantages, because they need complex cron daemon configurations and must run in different systems. Additionally, they require hard to maintain rpm and debian packages. Since the standard in EDGI monitoring is, in fact, settled by the format of XML files, one alternative to run previously prepared probes is to make the grid resources write the appropriate XML themselves. We started to change this with the ARC middleware. Despite producing the same XML output as the monitoring probes, ARC uses its own code to get a similar result. This makes monitoring simpler and more robust.

With UNICORE, we took the ARC model further ahead. We created a Java library that the UNICORE developers hooked to their code. This library allows UNICORE to directly call Java methods whenever events of interest happen, e.g., a new job is submitted to the 3G Bridge. In this way, neither we depend on external processes, nor we force grid developers to learn the internal details of the monitoring format.

The core of this library is the `XMLLogReport` class. The library also contains a few helper classes, namely the `ReportEntry` and the `OutputThread`. The former represents the data, while the latter, which extends the class `Thread`, periodically outputs the new data into XML (each 10 minutes by default), while deleting the old files (one week old by default). The `XMLLogReport` class contains the following public methods:

- `startReporting()`. This method initiates the `OutputThread` if it is not running yet.
- `stopReporting()`. Make the reporting thread finish after the next reporting event.
- `setReportsPath()`. Set the file system path where the thread should output the XML files to.
- `setCleanupAge()`/`getCleanupAge()`. Set or get the age of files that should be deleted on cleanup.
- `jobSubmission()`. Report the submission of a job. This data includes the identifier and the id of the job in the 3G Bridge. This allows the monitoring system, more precisely, the aggregator, to correlate all the identifiers of the same job across the entire grid infrastructure.
- `jobEntry()`. This method serves to register the entrance of a new job in the UNICORE grid.
- `jobChangeStatus()`. This method should be called when the infrastructure changed the status of some job or when it became aware of job status change on some other infrastructure.
- `output()`. Forces a report output. All the events that were created by the previous methods are outputted to a XML files upon invocation of this method.
- `cleanup()`. Deletes all files that are older than the threshold defined in `setCleanupAge()` or older than a default threshold if no other threshold has been set.

We also provided a `main()` method that uses the Java library for the sake of testing it.

V. CONCLUSION

We have described the motivation for and the implementation of a UNICORE extension as well as the corresponding monitoring environment, which directly supports desktop grids from within this service grid middleware. The extension will be integrated into the EMI environment. The stability of the extensions is ensured by several unit tests and also by EDGI's work package to test the developed infrastructure. Thus, an active cycle between test engineers and developers is established.

Additional concurrent project efforts port a lot of application to run on desktop grids, so that the UNICORE community can choose from a rich set of applications. These new resources will boost research, not only for those who use the additional desktop grid resources, but also by leaving more capacity for the rest of the users. In summary, the release quality, the broad application spectrum, and newly available resources make this extension a valuable contribution to the UNICORE community.

ACKNOWLEDGMENTS

***Abstract*—In the EDGI EU FP7 project a federation of Desktop Grid sites are built and maintained by the infrastructure team. These sites provide volunteer and institutional type resources in the range of hundreds of thousands of CPUs. The EDGI project offers these resources for the various gLite, ARC and UNICORE user communities and supports job execution with transparent bridging in the cases of gLite, ARC and UNICORE middleware. The paper focuses on the ARC side. A special bridging mechanism has been implemented in order to forward ARC jobs towards the Desktop Grid servers. The ARC bridge works in such a way that the A-REX execution service sees the Desktop Grid as a virtual batch system and users are able to submit to the Desktop resources seamlessly. The solution is scalable and includes handling large amount of files through a P2P distributed file system, called Attic. The paper gives a short overview of the EDGI infrastructure and introduces the technical details of the bridging mechanism. The introduced solution is also part of the EMI and EGI software stack to make it easily accessible for the ARC infrastructure providers.**

I. Introduction

Desktop Grids, such as pioneered by the Seti@Home project[1], are able to deliver enormous amount of resources at very low cost, often no more than the cost of a single server. On the other hand the cost in time is not that low. You have to understand the system, port your application, administrate the server, understand how to get your jobs onto the server and finally keep the volunteer community happy. While the gain in resources is certainly worth the effort the tasks are outside a normal research group's scope. One way to alleviate this problem is to bridge the Desktop Grid(DG) with the Service Grid(SG) infrastructure the scientist is used to. This way the scientist can exploit the DG resources the same way as his SG resources[2]. The EDGI project aims to further simplify this by making a federation of DGs available to the scientific community. The EDGI project will take care of the daily minutiae of setting up and running a desktop grid. It also supplies experts that can help port applications and finally aims to integrate the infrastructure with the major European service grids, ARC, gLite, and UNICORE. This way Desktop Grids providing computational resources in the range of hundreds of thousands of CPUs are transparently available to the Service Grid users. This paper covers the implementation of an ARC to EDGI bridge, that allows jobs to be submitted seamlessly from ARC to be run on the EDGI infrastructure. The paper will first introduce the EDGI infrastructure and the architecture of ARC before describing the ARC Bridge solution.

II. The EDGI infrastructure

This section gives a short introduction to the EDGI infrastructure. The infrastructure was first developed during the EDGES[3] project and later extended during the EDGI project, see [4]. Both projects supported by the EU FP7 framework. The goal of the EDGI infrastructure(see Figure 1) is to create and maintain a range of both public and institutional Desktop Grids and allowing these to transparently be taken advantage of by SG users, particularly the users of ARC, gLite, and UNICORE.

The EDGI infrastructure consists of a number of Desktop Grids ranging from purely institutional desktop grids at the University of Westminster to completely volunteer based grids like the BOINC based AlmereGrid. All of these DGs have been extended with a web service interface called the 3GBridge that allows uniform access for job submission and control across all the different DG implementation.

A second part of the infrastructure is the application repository. This repository contains reference implementations for all the supported DG applications and an overview of which applications and versions are supported by the different DGs in the infrastructure. These application have first been ported to the relevant DGs according to the requirements of the DG software (e.g. to the BOINC API) then the implementations are tested and validated by a partner in the EDGI project according to published guidelines, to ensure that they can be safely distributed to the desktop resources, and that any DG owner and volunteer can look up exactly what it is EDGI guarantees.

The Modified Computing Elements (MCE) are the bridges from the SG infrastructures to the EDGI infrastructure and the ARC MCE is the focus of this paper. The MCEs must forward jobs and return results between the two infrastructures as well as publish general information about the bridged infrastructure and the state of jobs running through the bridge.

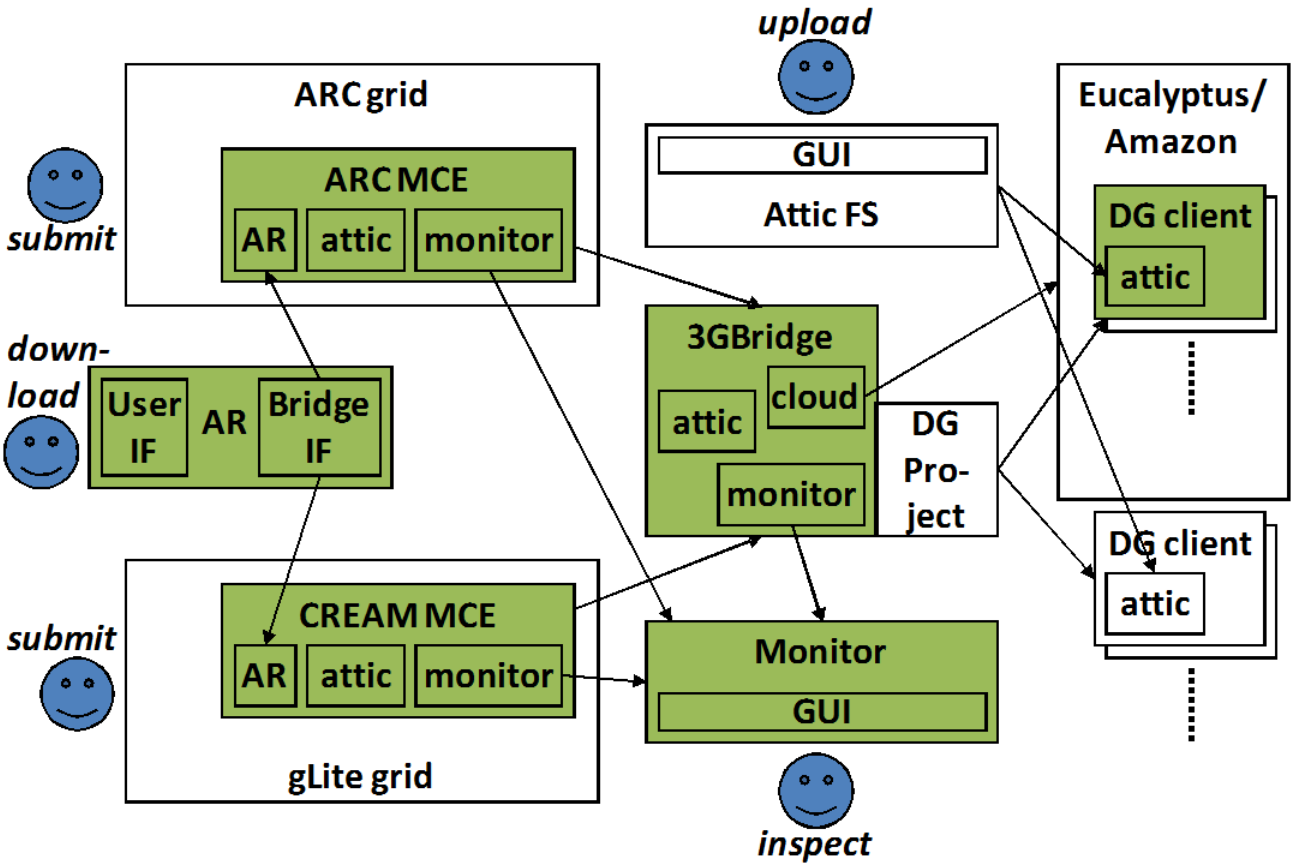

Fig. 1. The EDGI infrastructure

The Generic Grid-Grid Bridge (also called 3GBridge) is the standardized interface for Grids in the EDGI infrastructure. It is responsible for accepting jobs and passing them to the DG for execution as well as publishing job state and finished results.

The infrastructure is also able to leverage cloud resources (both institutional and paid for) when the user needs results faster than the DGs can provide or to smooth out the stochastic nature of the volunteer resources, see [2]. This functionality is provided by the SpeQulos service[5], also being developed by the EDGI project.

III. ARC

In this section we will describe only the parts of the Advanced Resource Connector(ARC) that are relevant to our discussion of the ARC to EDGI bridge and only to the necessary level of detail. Further information can be found in the references[6][7][8][9].

ARC originated from the NorduGrid collaboration initiated in 2001 and is now further developed and maintained by the European Middleware Initiative (EMI). It is one of the main middleware solutions used by the European Grid Initiative (EGI) in the European eScience infrastructure.

ARC aims to be a fully distributed non-intrusive service grid implementation. In practice this means that there are almost no centralized services and that there are very few requirements for a cluster to satisfy to be able to join an ARC based Grid. In fact the ARC server can be set up on a separate machine and act as a gateway to the cluster. The only requirement being that the cluster runs one of the many supported batch systems

(e.g. SLURM,PBS, etc.). The client independently contacts the different available servers and decides which to submit jobs to. There is no centralized brokering like e.g. gLite's WMS.

We will only discuss the ARC client and the ARC Computing Element (also called the ARC server) in this paper. Although a complete ARC based grid consist of many more services such as distributed data storage (Chelonia, LFC, etc.), accounting services (SGAS), and Virtual Organization services (VOMS), it has not been necessary to modify them in anyway and they are therefore not relevant to our discussion.

The ARC client is a small pluggable program that is available across many platforms (Windows, Mac, and several Linux flavours). It is responsible for submitting and controlling jobs. It can submit to standard and legacy ARC. It also has modules for submitting to UNICORE (using the OGSA-BES interface) and CREAM. The most important function of the client is brokering. Because there is no centralized queueing it is up to the client to find the best target for job submission. It does this by finding clusters that fulfill the job's requirements (such as available memory etc.) and then creating a ranked list based on a number of metrics e.g. queue length vs. available resources. It then chooses the most promising candidate. If the submission fails at the chosen candidate the client will try the next cluster in the ranked list.

The ARC server consists of a number of components:

1) A web service container called the ARC Hosting Environment Daemon (ARCHED)
2) A front-end that accepts job control and submission request and serves up job information.
3) A service that controls the progress of a job called A-REX.
4) Up- and downloaders that stage data in and out.
5) A cache for input files
6) Modules for connection to different accounting systems (e.g. SGAS)
7) A Run-Time Environment (RTE) repository.
8) Plug-ins for controlling the jobs in the batch system or Local Resource Management System (LRMS).

The main component of the ARC server is the A-REX service. This service is a state machine that controls the progress of jobs. In many instances the control of the job is passed from A-REX to an external service, when this external service finishes with the job, control is returned to A-REX and the job can progress to the next state. A-Rex for example transfers a job to the downloaders until all input data has been received. Job state and meta-data are kept in a special directory structure on the file system of the ARC server. This combines to make it very easy to modify the behaviour of A-REX through plug-ins. It is possible to configure what is called AUTHPlugins on the ARC server. These are programs that A-REX will transfer control to just before a given state. A technique that we have exploited in developing the ARC bridge, see sections IV-D,IV-E.

In keeping with the modular architecture of the ARC server the connection to the LRMS is also realized as a set of scripts or programs, colloquially known as a back-end, that will be triggered by A-REX in the appropriate state. These scripts must supply functionality to submit, cancel, query job status, and finalize a job on the local cluster. The scripts must also work with the RTE repository. The RTE repository works both as a simple list of the environments available on the ARC server and at the same time as a repository for the scripts necessary to supply such an environment. These environments can be physical, such as the machine has GPUs available for computation, as well as software, e.g. the cluster has MatLab available. The related scripts must then take care of in the first example modifying the submission so that it goes to the GPUs and in the second case managing licenses for example.

IV. Connecting ARC to EDGI

In this section we argue for the chosen design and describe the implementation of the ARC to EDGI bridge.

A. Client vs. Server side integration

The description in section III showed that because of the fully distributed nature of ARC there are only two possible places to integrate the EDGI access, either in the client or in the server. We will argue that the only reasonable option is in the server. Integrating the EDGI access into the client has the advantage of fully distributing the workload across all client machines thereby avoiding dedicated services and bottlenecks. The method has, however, two big drawbacks that make the approach infeasible. The first issue is that all data from SG resources would have to be staged through the client's machine, since the EDGI infrastructure has no knowledge of Grid storage protocols or authentication methods. While this is not a problem for clients that have access to high through-put networks, it will limit the client's usefulness in cases with low through-put or metered access. The second issue is more serious. As we saw in section 2 the EDGI infrastructure has no concept of user authentication. The security is based on only allowing certain IP numbers to pass through the firewall of the 3GBridge in question. This is clearly unmanageable as it would require each user to contact each resource owner to have his IP number allowed in the firewall, and it would rule out multi-user systems, because it would not be possible to separate users that have access from users that don't. Service grids, however, are built to tackle exactly these types of federated access challenges. The drawback of the server side approach is that it requires dedicated resources to act as bridges. This can be mitigated by making sure the bridge implementation is easily deployed and a standard part of ARC so that any community interested in taking advantage of the EDGI infrastructure can easily deploy their own bridge.

B. The 3GBridge as an LRMS

The ARC server presents a wealth of opportunities for integrating the 3GBridge technology. It could be implemented as a separate service hosted by ARCHED. It could be integrated directly into the A-REX service. The chosen approach is to implement the 3GBridge connection as an LRMS. This has the advantage of using well-tested production quality software for

a large part of the functionality of the bridge. At the same time, keeping the bridge as a separate module that will not interfere with standard ARC functionality, increases the probability that the bridge will be accepted by NorduGrid and EMI as part of the standard ARC package. The drawback is that the bridge will be implemented as scripted modules instead of being part of the main C++ code, thus sacrificing performance. The performance of the scripted back-ends are not a problem for ARC when acting as a front-end for clusters with the order of 10000 CPUS. The bottleneck in these system tends rather to be the data staging and file system performance. We therefore do not expect it to pose a problem for the ARC to EDGI bridge. In case the bridge becomes overloaded it is simple to set up another bridge and the ARC clients' brokers will automatically load balance across the available ARC bridges.

C. Software repository and Run-Time Environments

A challenge when connecting SGs to DGs is that a DG cannot run arbitrary software. The software must have been ported, often cross platform, and certified to ensure that it does not harm the donated resources. To that end EDGI has a repository of validated applications from which DGs can download and install. This repository is exposed in ARC through Run-Time Environments (RTE) on the bridge server. These RTEs are normally used to publish what software is available on the cluster that sits behind the ARC server, so they are ideal for publishing the EDGI repository. One difference is that an ARC server normally only serves one cluster, whereas in EDGI it functions as a bridge to a range of different DGs. One way to expose this to the ARC system is to create a queue for each underlying DG. It is however not possible to have different RTEs available for different queues and it would therefore not be possible to have DGs that had different applications on them. Another solution was therefore chosen, where the "queues" are exposed in the RTE naming convention. This way a user can simply choose an application in the ordinary fashion if the user does not care which DG it runs on, e.g. for the Dsp application: (runtimeenvironment="/APPS/DSP") or a named DG e.g. for the Dsp application on the DG called XW_LAL: (runtimeenvironment="/3GBRIDGE/XW_LAL/DSP").

D. Authentication and authorization

The ARC server authenticates using X.509 possibly extended with VOMS attributes[12] and authorizes on a per server basis. We would like to allow access to several resources through one single server without a user necessarily being authorized to all of the resources and therefore need to be able to authorize on a per application basis. To this end an AUTHPlugin was created. This plug-in is run before a job is accepted by the ARC server and checks the users VO affiliation against the RTE specified in the job script. The authorized VOs must be specified in the RTE on the server. This allows users to be authenticated on a per application and per endpoint basis. The check is done before the job is accepted which allows the ARC client to proceed to another available ARC server without alerting the user of a failure. This is not quite as elegant as the standard ARC approach where authorization is published in the information system allowing the client's broker to disregard resources where the user is not authorized. Unfortunately this approach cannot be used because the information system does not contain information on a per application basis.

E. Data staging

The DG part of the EDGI infrastructure and particularly the donated resources has no concept of the SG data protocols. It is therefore necessary that the ARC server retrieves any data from the SG infrastructure and makes it available using a protocol that is supported by the DG resources e.g. HTTP. At the same time it is important for performance reasons that the ARC server does not stage data that the DG resources can reach themselves. ARC normally stages all input data through special downloaders. These can be the same as the ARC server or separate nodes. These downloader nodes are assumed to be IO optimized and it is therefore better to stage data through them. This behavior is suitable for the ARC bridge except in the cases where we wish to postpone the staging e.g. in case of HTTP accessible files. An AUTHPlugin has been created for this feature. It is executed just before control is transferred to the downloaders. It simply removes URIs with protocols that are understood by the DG resources from the list of files to be downloaded, and instead store a list of them in a separate file. This file can then be used later in the job submission to restore the full list of inputs. In the other case the downloaded files and any files supplied directly by the submitter are moved to a staging directory. This directory must be published so that it is available to the DG resources e.g. using an HTTP server like Apache, but the actual method is configurable. The files are cleaned from the staging directory once the job they belong to has terminated.

F. ATTIC

Serving up the input data can put a heavy load on the ARC server, because all DG resources will have to get their data there. During the EDGI project a P2P file system called ATTIC[10] was integrated. This allows commonly used data files to be served in a P2P manner taking the load off the ARC server. Because the files will have to be transferred to ATTIC it is only an improvement if we know that the file is going to be used multiple times in the future. The only person able to make that decision correctly is the user. In our implementation it is therefore up to the user to transmit the file to ATTIC and then specify the ATTIC URI in the job description. The ARC server then uses the same pass through approach as described in the previous section for HTTP files. A future enhancement would be to tie the ARC server's input-file cache to ATTIC. The server could transfer big files that had been hit multiple times in the cache to ATTIC. This is no guarantee that they would be needed in the future and it would be worth the transfer but if we make sure to only transfer a file when it is being requested by a job there will be no net loss to the bandwidth requirements on the server.

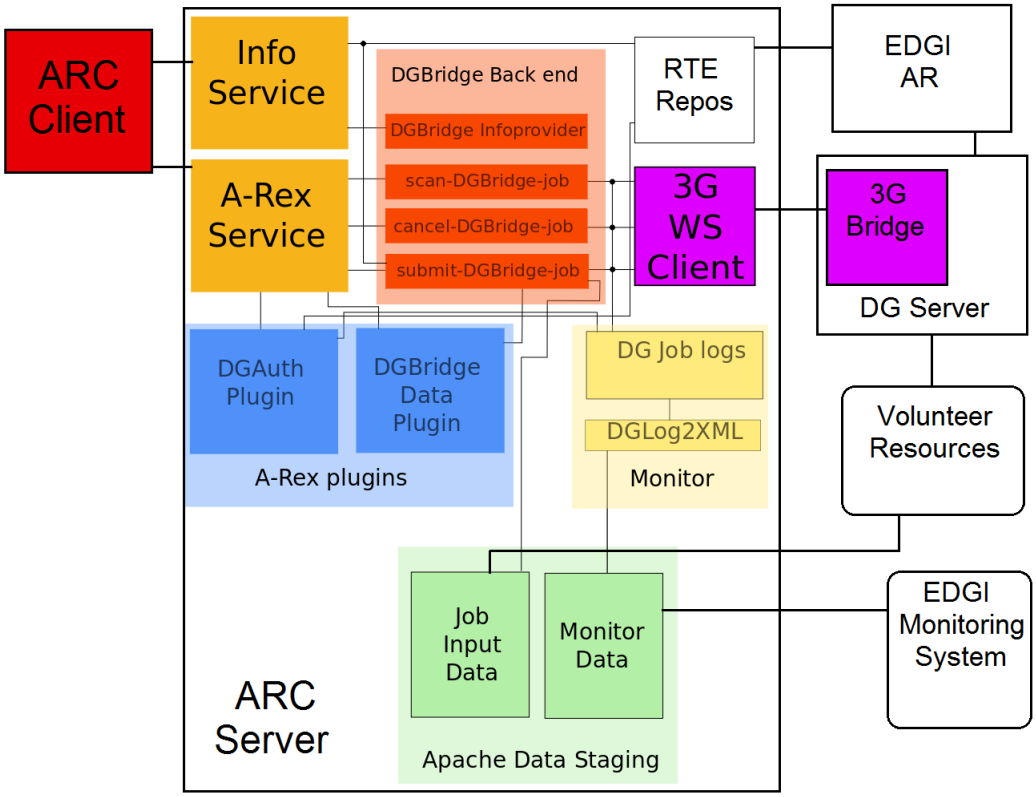

Fig. 2. The ARC bridge architecture

G. Monitoring

The EDGI infrastructure also contains dedicated resources for monitoring[11]. The ARC bridge must be integrated into the EDGI monitoring framework. This poses a challenge because the standard ARC server only publishes the current job state to the user while a job is running and does not produce the full accounting information until the job has finished and the final report is available from the LRMS. The EDGI monitoring framework on the other hand depends on the full information being available as the job progresses. All the back-end scripts and plug-ins developed for the ARC bridge must therefore output accounting information as jobs pass through them. This information is then periodically picked up by a dedicated script and transformed to the EDGI monitoring XML format and published using the same method as the stages job files e.g. using Apache.

H. Final architecture

Taking all the previously discussed points into consideration the final architecture of the ARC to EDGI Bridge solution can be seen in Figure 2.

The Info service and A-REX service are the standard ARC components. Only a tiny addition to the interface between A-REX and the LRMS back-ends was needed. This addition is now a standard feature of the LRMS API in ARC. The 3G WS Client component is the new client developed within the EDGI project and contains scalability improvements and Attic support. The shaded boxes contain the components that are specific to the ARC Bridge.

The red box contains the LRMS back-end, called ”DG-Bridge back-end”. These are the scripts that are run by A-REX to control a job, as well as by the info service to supply information about jobs and the state of the DGs to the ARC information system, see section IV-B.

The blue box called ”A-REX plugins” contains the plugins that modify the behaviour of A-REX. These are used by the bridge for allowing per run time environment (RTE) authorization and for bypassing the normal data staging behaviour for Attic and HTTP files, see sections IV-D and IV-E.

The yellow box called ”Monitor” contains the monitoring components. The back-end and the authorization plug-in write events to the DG job logs, and they are regularly picked up by the DGLog2XML service and converted to the EDGI monitoring format and published, see section IV-G.

The green box called ”Apache Data Staging” contains the data that must be made available for the 3G Bridge and the monitor, such as job input data and the generated monitoring log files. These are handled by the back-end and the monitoring service respectively, see sections IV-E and IV-G.

V. Conclusion

The solution described here-in has been developed, tested and deployed in production within the EDGI project. The developments have also been accepted by both the EMI project and NorduGrid and are now a integral part of the ARC server software and the EMI releases. This means that an ordinary ARC server installation is capable of acting as a bridge to the EDGI infrastructure, by simply specifying it in the configuration. The EMI release containing the ARC bridge has also been accepted by EGI for UMD (Unified Middleware Distribution). This means that all infrastructure providers within EGI are able to easily and transparently connect their SG users to the resources available in the EDGI infrastructure.

Further work is focusing on performance and reliability measurements and on porting popular ARC applications to the EDGI infrastructure, to fully take advantage of the available resources.

Abstract - Complexity of design, development and deployment of software for wireless sensor networks is high, and even more exacerbated by ad-hoc nature of some network deployments and the need for high adaptability to varying internal and environmental factors. In this paper the authors present a model of distributed application based on a set of application specific roles/functional modules. Deployment and runtime adaptation of application topology is achieved by controlling role activity on each of the network nodes, thus forming a functional application instance for a specific sensor network. Application control decisions are delegated to agents located on sensor nodes, and based on a set of role-specific utility functions. Existing wireless sensor network system for vehicle detection and classification is refactored according to the proposed model, modeled in a sensor network simulator and simulation results presented.

I. INTRODUCTION

Design and development of wireless sensor network (WSN) systems proves to be more difficult than development of 'regular' embedded systems for a number of reasons. Two of the most important ones are the need to provide high level of adaptation to both internal and external factors influencing individual nodes and communication links, and to realize local decision making mechanisms based on a restricted (local) view of the network and environment state. Lack of node location information due to ad-hoc network deployment, large number of nodes and/or unavailability of location services complicate the problem even more.

We propose an approach where a complex distributed application for wireless sensor network is decomposed into a set of functionally connected roles. Network nodes are able, in accordance with functional, structural and runtime constraints, to host a number of active roles, thus forming a functional and, if possible, near-optimally deployed distributed application.

Role selection, however, remains a strictly local and information-scarce process, where a control mechanism decides on a subset of roles the local network node should host at any given moment. Our approach decouples role functionality from role management, employing an agent-based approach to distributed decision making. Agents, one at each network node, select the most valuated subset of roles according to a set of pre-defined utility functions and information acquired from host node and neighboring agents.

The described approach is employed in re-factoring of the ad-hoc deployed vehicle detection and classification system, where a small set of roles and their relations is defined, as well as the set of utility functions for agent-based role management. The performance of the deployment—time role allocation is tested in the wireless sensor network simulator.

Acquired simulation results are compared with the results acquired from the application specifically developed for calculating the optimal role deployment using the 'omniscient' (global) approach to sensor network. The application uses a genetic algorithm for finding the optimal or near-optimal role allocation for a given network topology and node states.

Section 2 of this paper presents the related work. The role model and agent-based application topology control are introduced in Section 3. Section 4 describes the example application for vehicle detection and classification refactored according to the proposed model. Section 5 presents the GA-based evaluation application and Section 6 the results of simulation of test application for a variety of network topologies. Section 7 concludes the paper.

II. RELATED WORK

Generic role assignment problem [1,2] has been addressed by means of a role definition language, a distributed role assignment algorithm and a role compiler. Role decisions rely on a set of static rules distributed on all network nodes and property values collected from host and surrounding nodes. No decision process adaptation is envisioned.

Variations of a role-assignment approach have been developed, focusing on particular aspects of the methodology such as energy efficiency [3] or on-demand assignment [4].

The notion of neighborhood has been adapted to wireless sensor network domain as a means of abstracting the network regions with shared data or collaboration [5,6]. However, used abstractions (regions, neighborhoods) do not use explicit role decomposition.

ROLE-BASED APPLICATION MODEL

A. Wireless Sensor Network Model

Wireless sensor network abstraction is defined as a graph G = (N, L), where N is a non-empty set of vertices n_i representing wireless sensor nodes and L is a set of edges denoting communication links between pairs of nodes (n_a,n_b), $n_a \neq n_b$, In this simplified model undirected communication links are assumed, where in reality, directed (asymmetric) links between nodes can often be observed [7,8]. Sensor network topology is mostly determined at deployment time, but remains dynamic during system lifetime due to various internal (node failures, de- synchronization) and environmental factors (variability in signal propagation, interference, node relocation etc.).

A neighborhood of node n_i is defined as a subset of nodes from N having direct communication links with n_i: Nbg(n_i): (n_j: (n_i, n_j) ∈ L). If undirected communication links are assumed, then the reciprocity exists: if n_i is a neighbor of n_j, then n_j is also a neighbor of n_i.

Each wireless sensor node is composed of functional entities (e.g. processor, communication subsystem, memory, sensors etc.) and resources. Resources can be constant (e.g. processing power) or variable (e.g. available memory or remaining energy). The model assumes all the nodes posses a core set of functional entities, but can differ in additional entities such as number and type of available sensors, fixed or renewable energy source etc. All node resource levels are represented as a node state.

B. Roles

All but the simplest WSN applications require distribution of different parts of overall application functionality on more sensor nodes. There are several key factors that determine such distribution:

- Capability factors: capability of a node to perform required specific functionality (required sensor, required amount of memory etc.).
- Spatial factors: dispersion and/or density of functionality in area covered by sensor network.
- Temporal factors: adaptation of functionality to changing internal and/or external conditions (e.g. node state, appearance of observed phenomenon etc.).
- Functional factors: existence and/or composition of a set of functionalities in order to provide desired overall application functionality.

A role is an abstraction of a part of application functionality that forms a coherent whole with regards to data acquisition and/or processing. Application role has well defined interfaces with other roles and with host node by which data and control information is exchanged.

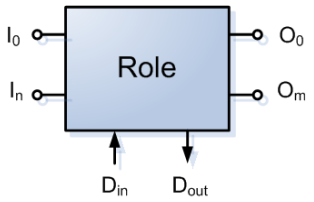

Figure 1: Role model

A role is represented as a tuple:

$$R = (I, O, S, D, F, X, x_0), \quad (1)$$

where I is a set of input interfaces, O set of output interfaces, S set of data sources, D set of data drains, F a set of transformation functions, X set of role states and x0 an initial role state.

Each input and output interface is characterized with a single message type, thus determining possible connections between roles. Reception and transmission of messages using interfaces, data transformation and state transitions are performed asynchronously.

A role requires functional support from the sensor node (e.g. radio subsystem, sensor), and it consumes, temporarily or permanently, a number of node resources (e.g. memory, energy).

C. Role Composition

Role-based application is defined as a directed acyclic graph A = (R, C), where R is a set of vertices representing application roles and C is a set of directed edges representing connections between roles. The graph represents data and control flows among application roles. Each role has an associated cardinality, i.e. how many times it can appear in the application topology graph when the role composition is mapped onto a WSN graph. The following cardinalities are defined: (exactly) 1, 1..n, 0..n and 0..1.

D. Topology Control

Application topology is defined as a mapping of roles and links among roles onto vertices and edges of a graph representing the sensor network. One sensor network node can host a (possibly empty) subset of application roles. To be valid, such mapping must respect the following constraints:

- Compositional constraints - defined by a role composition graph.
- Structural constraints – defined by underlying sensor node capabilities (for a certain role).
- Cumulative constraints – cumulative availability of local resources for a certain role subset active on a particular sensor node.

In addition to the previously listed hard constraints, application topology should also reflect the application level policies such as coverage, minimization of energy consumption (application and/or node level) etc.

The mapping (or role mapping) process is inherently a continuous and localized process performed on every sensor node in the network. The decision mechanism and role functionality implementations are decupled, allowing different mechanisms to be used for application topology control. Such control mechanism, however, must rely only on information gathered from local state information (node, roles) and information available in the node's neighborhood.

Mapping a role on a WSN node implies activating a role implementation already present in the node's software. There is no code migration, replication or role state migration due to high time and energy requirements for such activities.

E. *Agent-Based Topology Control*

An agent-based approach [9] to application topology control assumes existence of one agent at each network node. The agent determines the current subset of active roles on a node by evaluating all feasible role subsets for that node (determined by compositional, structural and cumulative constraints) and selecting one on the basis of maximal income. Agents are self-interested and are trying to maximize their profit according to the system-wide defined social rules. Used rules are mostly application-specific, but in general define three types: (a) reward functions for awarding activity of a certain role or a subset of roles; (b) penalty functions for penalizing activity of a certain role or a subset of roles; and (c) mandatory behavior of agents (e.g. sharing current node configuration with neighboring agents).

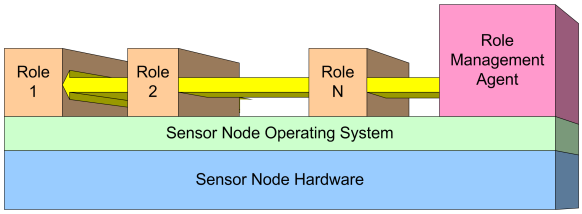

Figure 2: Agent-based role management

Reward and penalty functions are based on the locally available information: node state (e.g. resource levels, such as remaining energy), role states and properties (e.g. energy consumption in active mode), system history (changes in role activity) and information provided from the neighboring agents (e.g. concentration of roles on neighboring nodes). The combination of roles with the highest valuation is selected for the currently active role subset on the controlled node.

A series of local decisions made on every network node should, in ideal case, result with the optimal role distribution – application topology – for a given wireless sensor network deployment and current internal and external conditions. In reality, the system should (a) converge to a stable topology as soon as possible, (b) retain stable topology or quickly converge to a new stable topology on a node reconfiguration, (c) stable topology should be reasonably close to the optimal topology.

III. EXAMPLE ROLE-BASED APPLICATION

A. *Vehicle Detection and Classification Sensor Network*

Vehicle detection and classification (VDC) application is a typical example of an area-surveillance sensor network application with a medium amount of in-network processing and single-point data collection and extraction from the network [10]. Location information (absolute, relative or partial) may or may not be available in such type of sensor network, depending on node capabilities and specific deployment conditions. In this VDC application sensor nodes (no location information) perform data acquisition and basic processing (amplitude-frequency domain transformation). Observations are transferred to the main node where further data processing, analysis and classification is conducted. The application uses star network topology where observations are transferred to the central processing node in one packet hop.

The main drawbacks of such architecture are short system lifetime, sharp functionality degradation towards the end of lifetime, need for controlled deployment and reduced spatial coverage.

B. *Refactored Role-Based System*

An improved version of the original application was envisioned to allow simple ad-hoc deployment of network nodes and extended spatial coverage by using multi-hop communication. Such network is to address problems of self-organization, self-adaptation and extended lifetime by smart usage of available node energy (from finite supplies or from energy-harvesting sources). The following roles are used in a simplified application model:

Detector (D) – a node periodically samples sound and determines if the sound level is above regularly observed noise level; if elevated level is detected, neighboring Sampler roles are alerted.

Sampler (S) – a node, upon an alert received from one or more Detector roles, samples sound using node's microphone and performs amplitude-frequency domain transformation. Acquired frequency spectrum information is used for vehicle type classification, and the resulting information is transferred to the Gateway role via Forwarder nodes.

Forwarder (FW) – routes vehicle information messages from Sampler roles to the Gateway role down the gradient field. A path from Sampler to Gateway role can contain from 0 to n Forwarder roles.

Gateway (GW) – one or more special-purpose nodes in the network used to extract information from the network.

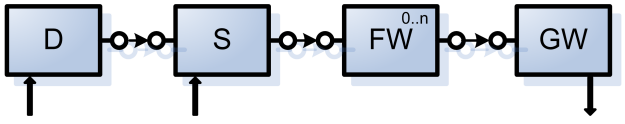

Figure 3: Role composition for VDC application

C. Neighborhood

Social rules mandate agents to provide limited local information to the neighboring agents. Such information consists of a list of active roles on a particular node and a number of nodes within that node's neighborhood. Information is periodically broadcasted by node agent and received from other agents on neighboring nodes. This information is also used for establishing and maintaining local perception of node's neighborhood membership. Collected information is processed and added-value information is used as input to decision-making process of role control agents.

D. Utility Functions and Role Selection

Due to role resource demands and cumulative constraints on local node resources, a node is allowed to host only one active role at a time. Active roles are selected by a local agent on the basis of profit maximization, determined by periodical evaluation of utility functions for each role a node can host (dictated by structural constraints).

Detector (D) role:

$$U_D = \alpha_D \cdot (1 - e^{-\frac{\overline{nbr}}{nbr}}) + \beta_D \cdot e^{-(\#d - \overline{d})^2}, \qquad (2)$$

where nbr is the number of nodes in the node's neighborhood, $\overline{nbr}$ is the average number of neighboring nodes for the node's neighborhood, $\#d$ is the current number of nodes in neighborhood with active role D, $\overline{d}$ is the targeted number of nodes with active role D in the node's neighborhood, α_D and β_D are weight parameters. The first part of the utility function aims to position Detector roles at graph edge nodes (lower node degree than average degree in the node's closed neighborhood), i.e. at the sensor network perimeter nodes or nodes surrounding in-network holes. The second part of the function tries to maintain a desired concentration of nodes hosting a particular role in a one-message-hop radius.

Sampler (S) Role:

$$U_S = (\alpha_S \cdot (1 - e^{-\frac{nbr}{\overline{nbr}}}) + \beta_S \cdot e^{-(\#s - \overline{s})^2}) \cdot R_s, \quad (3)$$

where the first part of the utility function tries to position Sampler roles at nodes deeper within the sensor network, and the second part tries to maintain a desired role concentration. Parameter R_s represents the mandatory requirement that any S role must have at least one FW or GW role and at least one D role in its neighborhood (R_s is a binary parameter that takes only value of 0 or 1).

Forwarder (FW) Role:

$$U_{FW} = \alpha_{FW} \cdot (1 - e^{-\frac{nbr}{\overline{nbr}}}) + \beta_{FW} \cdot e^{-(\#fw + \#gw - \overline{fw})^2} \cdot \log \Delta, \quad (4)$$

where the first part of the function tries to position FW roles at nodes having a higher degree than surrounding nodes, and the second part of the function tries to maintain a desired concentration of FW roles in the neighborhood. Factor Δ represents the maximal communication distance (in message hops) among the nodes in the neighborhood; the larger the distance, the more FW roles are needed to reduce communication cost.

Gateway (GW) Role:

The Gateway role is a predefined role for a special sensor node type with enhanced communication (and processing) capabilities. Such a node, in a VDC application scenario, cannot have any other active role than GW.

Role Selection:

The role selection process is a periodic process performed by the node's role management agent. Agent calculates potential income based on utility functions for D, S and FW roles. A fixed penalty P_{switch} is subtracted from non-active role incomes to reduce frequent role switches due to minor differences in valuations.

A role with the highest potential income is selected to become a new/old active role, but only if the potential income is higher than a T_{select} threshold. If the defined threshold is not reached by any of the roles, the node is left role-free. In such a case (network density is high or no required functional composition can be established), nodes are kept in low energy consumption state and activated when other surrounding nodes fail.

IV. GENETIC ALGORITHM FOR OPTIMAL TOPOLOGY IDENTIFICATION

A. Genetic Algorithm usage

Every agent determines locally optimal role combination for given node environment state, thus making agent-based approach to topology control inherently a *bottom-up* approach*,* To evaluate the quality of results provided by the agent-based approach, especially for large sensor networks, it was necessary to model the problem from the global, omniscient, point of view. Top-down approach to topology control problem, although infeasible in practice, should enable identification of an optimal or near-optimal role allocation for a given sensor network at a given moment in time (determined by the global state of the network in a given moment in time).

Due to large number of possible role allocations the algorithm must evaluate, a standard exhaustive search algorithm is not applicable but for the simplest networks. Consequently, the genetic algorithm (GA) was employed to find nearly optimal application topology.

B. The Basic Elements of the GA

In a genetic algorithm, a population of strings (called chromosomes), which encode solution domain (consist of so called *individuals*), evolves toward better solutions. It requires fitness function to evaluate the solution domain. At the end, the algorithm reaches (near-)optimal solution.

Chromosome, which encodes one solution to an optimization problem, is represented by one-dimensional array of values where a value represents node's active roles' combination. Array index encodes node's unique ID in the sensor network topology.

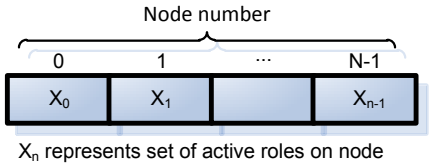

Figure 4: Chromosome structure

A fitness function evaluating VDC application's solution domain consists of 2 criteria: *total area* of overlap and the *shortest path* between observer's node hosting sampler (S) role and node hosting a gateway (GW) role.

Operation of the GA heavily depends on fitness function design. The following fitness function is used:

$$f_{fitness} = \alpha \cdot \left(P_{overlap} \cdot e^{-\beta \cdot d_{hop}} \right) \qquad (5)$$

where parameter $P_{overlap}$ represents total area of overlap between 2 nodes, d_{hop} represents shortest path (distance) between sampler role node and gateway role node measured in a number of message hops, α and ß are weight parameters.

GA selection operator selects individuals for crossover operator from the current population. Among many selection algorithms tested, a *roulette wheel parent selection* algorithm in our case proved to be the best solution.

In addition to finding optimal role allocation for a given sensor network and current state, the algorithm provides an *allocation optimality factor* that enables a quantitative comparison of role allocations. The developed utility application takes an application topology from external source (file), finds the optimal topology and calculates fitness factors for both of them.

V. SIMULATION RESULTS

A. WSN Simulator

Described VDC sensor network application and the underlying concept of agent-based application topology control has been tested in the simulation environment. A general-purpose WSN simulator was developed in Java language, allowing simulation of large and heterogeneous sensor networks. The simulator is event-based, supporting multiple radio models, power sources, simulation of different environmental factors (both for power harvesting and for different sensing modalities) and flexible extension mechanism.

B. Simulation Parameters

The following parameter values for utility functions were used: α_D=0.7, α_S=0.7, α_{FW}=0.7, $ß_D$=0.01, $ß_S$=0.3, $ß_{FW}$=0.1, $\overline{d}$ =0, $\overline{s}$ =0, $\overline{fw}$ =2, P_{switch}=0.01, T_{select}=0.4.

A simplified version of radio model was used (uniform communication range, packet-level loss probability estimation), all nodes had unlimited power supply. Nodes were static and had no location information available. Neighborhood information packets are broadcast by node's agent every 2 minutes.

C. Sensor Network and Application Topologies

Performance evaluation of the MAS-based approach to VDC application has been conducted on a number of sensor network topologies; from highly controlled and regular shaped to randomly generated ones. If feasible, results from MAS- and GA-based approach were compared. In this section three test topologies and respectful role assignments are presented: linear, modified grid and random topology.

Figure 5: Linear topology

On a linear topology sensor network (Figure 5), a single GW role is fixed at node 4; other roles have been assigned correct locations by node agents, in accordance with the role composition graph on Figure 3. GA- and MAS-based approaches yield the same role placements.

In the modified grid topology (Figure 6) the challenge for the MAS-based approach is to ensure communication paths from all S roles to a single GW role located at node 0. Also, each D role must be located at the edge node, and each S role must have at least one D role in its neighborhood. GA- and MAS-based approaches yield almost the same results for this topology.

MAS-based approach, in the current form and with parameters used, reveals its weakness when applied to large randomly generated networks with large in-network holes (Figure 7). When allocating roles for nodes with lower average degree that are connecting areas with higher node densities (for example nodes 20 and 28 in the network center), agents tend to select role D over role FW. As a consequence, VDC system is fragmented into sub networks of densely node-populated areas, drastically reducing effective area coverage to only a sub network containing the GW role.

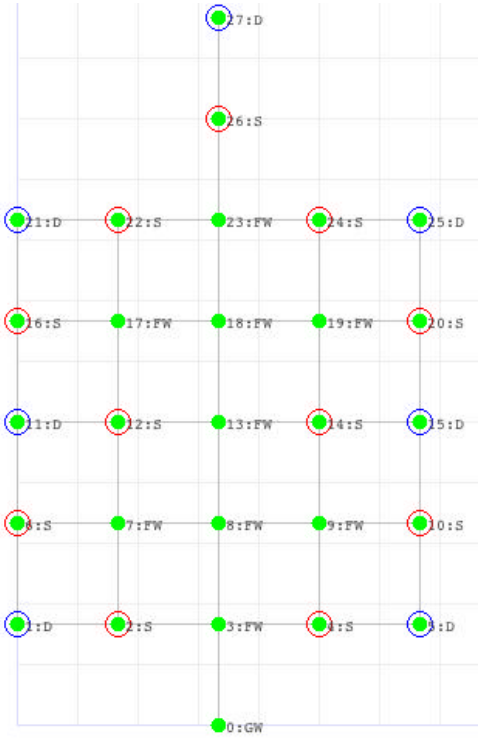

Figure 6: Modified grid topology

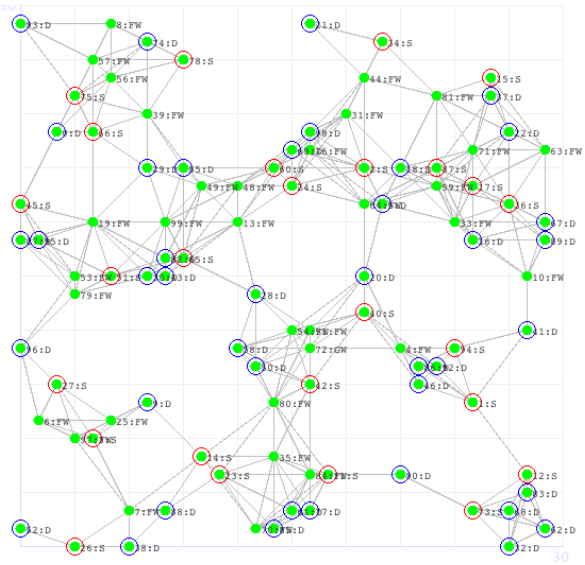

Figure 7: Random topology

VI. CONCLUSION AND FUTURE WORK

In this paper we proposed a method of decomposition of WSN application functionality into a collection of roles. Allocation of roles to sensor nodes is performed by a multi-agent system. Self-interested agents, located on each sensor node, try to achieve optimal role allocation for a given network and node conditions, by maximizing their income. Simulation results of a role allocation for a sample vehicle detection and classification application show promising results on a number of test network topologies, however there are problems in correct role allocation for networks with large in-network holes.

Future work will address both the general approach to system modeling and utility function synthesis and introduction of new elements in role allocation process, such as additional node and network properties (energy levels, absolute node density, cooperative energy conservation) as well as resilience to dynamic environment conditions (node failures, communication availability, asymmetric communication links etc.).

e-mail: tin.petrovic@fer.hr, mario.zagar@fer.hr

Abstract - Distributed computer systems of microcontrollers with environmental sensors, known as wireless sensor networks, allow real time monitoring of complex events. Over the last ten years this technology is slowly being applied in many areas such as: agriculture, environmental monitoring and urban planning. However, the technology has yet to see a strong commercial application because of a: lack of universal norms, short lifetime cycle and security concerns. This paper will describe the basic characteristics of a wireless sensor network, followed by a list of different types of security problems that wireless sensor networks face. For each problem, a recommended method for improving security is given, along with all the downsides of such a method. After reviewing the current state of the technology we will propose a new method to improve security and intruder detection for certain types of networks.

I. INTRODUCTION

Over the last two decades the cost of computers has been steadily dropping. This has created a situation where the problem: "Do we have enough computational power?" has changed to: "How can we efficiently use all the computers we have?" Wireless sensor networks (WSNs) are one such successful example. In essence they are a distributed computer system, made up of small computers. Each such node is made up of several components. Firstly, a microcontroller that provides the necessary computational power. An autonomous power supply: like a battery or an energy harvester. Environmental sensors that provide data about monitored events and lastly a radio for wireless communication. Such a node can monitor certain parameters, for example temperature and then wirelessly communicate the data to a similar node nearby.

If a large number of such nodes are used at the same time, a network of distributed wireless sensors can be formed. This is mostly done Ad-Hoc. As a node is turned on, it tries to find other nodes nearby and connect to them. Depending on the given parameters the network can take almost any shape. Within the network, data can be shared by the nodes to make some sort of decision or it can be aggregated to a single node. In the first case an agent system is usually employed so the network can make smart decisions (e.g. wild fire detection [1]). In the other case, data from all the nodes is gathered to a single node: "a sink". In some situations the sink is a node just like any other. More often the sink is a more powerful version of a node or is not limited to the same energy conservation needs. Regardless of the type of sink, data aggregation methods imply that the data will only be gathered with the network and processed outside of it.

Every WSN is designed with a specific goal in mind. The last ten years have seen a wide application of WSNs in many different areas. Some of which include: landslide detection [2], glacial monitoring [3], vineyard and olive tree monitoring [4,5], wildlife tracking [6], health care [7,8] and a large number of "Internet of Things" projects backed up by governments in the last few years. This trend shows that the potential of the technology has definitely been recognized. But before we can see a strong and wide ranged commercialization of the technology there are three big areas that still need work.

The lack of universal standards and norms is still the biggest problem. This causes almost no interoperability between different products and a lack of focused development both in the industry and the end-user services. The lifetime of most battery powered networks is still shorter than the required lifetime cycle. This is especially problematic in cases where the network is supposed to run for an uncertain amount of time without the possibility of maintenance. The last problem is that of security.

This paper will focus on analyzing the most commonly known security threats and attacks on WSNs. In the first part, a short reason as to why security in WSNs is important is given, along with technology restraints and a list of all attack that will be covered. The majority of the paper then describes attacks on WSNs and security countermeasures as described in different works on the subject. By presenting different recommended countermeasures for each attack as well as all the benefits and downsides of such solutions, we will try to give a clear overview of the current state of the technology. At the end of the paper we suggest and talk about a new method to improve WSN security by way of a mobile sinks.

II. SECURITY CONCERNS

As WSNs are used for more and more important tasks, the problem of security becomes more important. At first glance it is easy to argue that only some types of networks require security measures. For example: a network that just takes readings of environmental information in a certain area so that secondary weather patterns can be observed, like the amount of sunshine, could be considered a network that does not need strong security. On the other hand a body sensor network which monitors the possibility of a heart attack is intuitively considered a

type of network which should be protected from tampering. But if someone was to link the information of the first network to land values, a problem quickly emerges. By simply tweaking the information so that the number of sunny days is raised or lowered, someone could easily raise the value of his real estate or lower the value of someone else's before purchase. Most technology quickly grows beyond its original concepts and starts serving as an infrastructure for something else. For this reason security is something that is required for every type of WSN.

Before looking into how some of the stated problems can be solved, one should have in mind some of the other characteristics of WSNs. In concept each node should be small, cheap, last a long time and have a long communication range. Of course, this is in itself contradictory, more so because the focus is mostly on making the nodes as cheap as possible. This is a current trend in the industry that will most likely not change in the next few years. By having cost as a fixed parameter, it is impossible to easily change any other characteristic without harming something else. For example, additional hardware security modules and multi-frequency radios can solve many problems but can easily also double the price of a node. Also, using solutions that increase the complexity of the network will indirectly harm all the characteristics of a network. So, clever solutions are usually needed. For example: expected lifetime, which translates to energy efficiency, is prolonged by better sleep protocols and algorithms or by energy harvesting methods. Different solutions are applied to different problems always having in mind not to put more strain on something else.

The following is a list of the most studied attacks on WSNs. Attacks are grouped based on where in the network they occur, using a bottom up approach. This paper uses a simple taxonomy and does not go into great detail about all the possible types of attacks [9, 10, 11].

III. ATTACKS ON NODES

Unlike most other distributed computer networks, WSNs are mostly unsupervised. A lot of the time nodes are placed in hard to reach places with long periods without maintenance. This makes them easy targets to a wide range of attacks.

A. Physically destroying a node

The cheapest and easiest way to attack a node is to destroy it. Hitting it with a hammer, using a fridge magnet or tearing off the antenna are all very effective low-tech ways to hamper the work of a network. There are a few ways to counter this. Protecting the sensors in some sort of a protective casing is usually the most cost effective solution. Nodes that are placed in open environments are already threatened by a lot more than malicious human intent. Rain, flying debris and temperature oscillations are just some of the problems. There are many off the shelf solutions for protecting sensitive electronic equipment and wireless sensor nodes are no exception. This does raise the cost per node of a network but is usually something that cannot be avoided. A different solution is also to expect that nodes will be continuously destroyed. Depending on the network, ultra-low cost nodes can be used. Such a network could easily have over a thousand nodes where only 10% were in actual use in any point of time. So if someone was to destroy a hundred nodes, there would still be a close to 90% redundancy. This solution it a bit more theoretical then practical, since it requires a highly scalable network made of biodegradable nodes.

B. Physical corruption

A much harder but with significantly greater implications is a physical corruption attack. With sufficient time and knowledge it is possible to gain access to a node. This could mean gaining access to the nodes memory, being able to augment the programing board or reprograming the node to do a different task. These attacks are characterized by the node not being destroyed but altered in such a way that suits the attacker. Depending on how prepared the attacker is and what type of network he is attacking, it may even be possible to execute the attack without it being immediately detected. With the right equipment it may even not be necessary to remove nodes from a network to perform the attack.

1) Memory access

Memory access allows the attacker to see any security keys as well as any sensor data that has been stored on the node. This type of attack is usually done "offline". The node is simply taken from its location to a laboratory and then using different tools either scanned or just accessed. Fully preventing this type of attack is usually impossible. Solutions tend to be too expensive (adding a hardware security module) or too complex to implement (scalable memory erasing). A better option is to make sure that knowing the content of one or a few nodes does not give the attacker any useful information. Probabilistic key distribution methods or segmented data distribution within a workgroup are some such methods. These solutions mitigate the problem to the network level and can only be done on networks with a large number of nodes. Because of this, some types of networks like sparse mobile sensor networks with mobile sinks have no way to guard against such attacks.

2) Programing board access

Augmenting the programing board could allow an attacker to completely monitor the work of node without being detected. Due to the complexity of such an attack and lack of real examples, such attacks are usually discarded as improbable. Most of the components on the sensor and communication board are highly sensitive to voltage changes, so any infield work has a high probability of destroying the sensor.

3) Node takeover

Reprograming a node is in many ways similar to making an outside attack on a single computer in a classic computer network. The node is accessed, usually via a programing board or wirelessly and its code is changed. After which, depending on the attackers plan, the node may start stealing the data or disrupting the work of the network. The recommended way to counter this is to disable writing in the memory of the node, once the program has been uploaded. The downside of this

approach is that all nodes must be programed in a lab and then deployed to do only one task after which they will be discarded. They cannot be reprogramed, changed or upgraded in the field by over-the-air programing. All this makes the network inflexible and greatly reduces its potential.

Beside the given solutions for countering physical corruption there are other methods at the network level that focus on intruder detection. The easiest method is to increase the frequency at which each node in the network is sending data. All successful physical corruption attacks that do not wish to be detected must be executed during the sleep phase of a node. If a node is active every 30 seconds instead of every 5 minutes a successful attack will be extremely difficult to carry out. Unfortunately this greatly shortens the lifetime of a network. A different approach is to randomize the time when a node sends data, but this greatly increases the complexity of the network. Another method is blacklisting within workgroups. In a large network, a number of nodes are grouped together usually by locality. Workgroups like this basically work as one sensor with added redundancy. All the data is aggregated to one node, which does not always need to be the same node, and then a decision is made. If a single node is found to be continuously sending bad data, it is blacklisted and isolated from the network. This kind of method can be used for other things besides security so it does not greatly increase the complexity of a network, but it does open the doors for other attacks that will be covered later on.

IV. ATTACKS ON COMMUNICATION PROTOCOLS BETWEEN NODES

Since all communication between nodes in a WSN is done wirelessly via radio, potential attackers can use a number of different denial of service attacks. Intercepting and sending fake communication messages is also easy since communication is usually done by broadcast. Smart algorithms and network redundancy help maximize network availability and cryptography ensures privacy and authenticity.

A. Denial of service

Denial of service attacks in WSNs are attacks that disrupt the normal sending and receiving of messages within a network .To execute such an attack, the attacker needs a radio capable of transmitting and receiving specific radio signals and some knowledge about the network he is attacking. This paper will only be looking at denial of service from a communication perspective as a result of an attack.

1) Message corruption

To establish a connection between nodes at the start or to communicate data, all nodes must send radio messages. This exchange usually happens periodically in certain predetermined timeslots. If the attacker knows when a node will start to send or receive data, all he needs to do is send his own signal. The original signal then becomes overwritten and the message is discarded. This will force the nodes to retransmit, thus forcing it to expand more energy. If there are no control mechanisms a node can even be completely drained of power. Depending on the network, loss of data may also be an acceptable option, but this only works in cases where more than one node is sending the same data. There are some workarounds for this. Even in a basic WSN, which gives no focus to security, radio interference can happen. Most protocols counter this by randomly changing the radio frequency at which they communicate. This had proved to be an effective and very reliable method of communication even within areas of heavy electromagnetic interference. Research is also currently being done on ways to extract useful data from a scrambled signal, but as of yet strong commercial applications do not exist.

2) Jamming

If the attacker does not have detailed knowledge about a network, there is still a very simple method to disrupt a network. Since all the protocols used by WSNs operate in the unregulated radio specter area, all the attacker needs to do is jam the entire radio specter. A strong radio signal which continuously broadcasts on all frequencies will completely cripple the network. The only situation where this can be somewhat countered is on the network level in case of large networks with a large number of nodes. Once a jamming signal is detected, the network will try to re-route all the data using the nodes that are outside the influence of the jamming signal.

B. Attacks on communication protocols

Secure communication between two nodes in a WSN has all the same requirements as in any other network. On the other hand, implementing such mechanisms is much harder. Limited memory, processing strength and lower bandwidth are all constraints that must be taken into account. There are a large number of papers published in this area suggesting different approaches of handling security as well as many surveys about different implementations [12]. To keep this paper concise, only some points will be presented.

Securing communication between two nodes in a WSN requires that criteria be met just like in a classic network. To achieve privacy and authenticity, cryptography is used. Since some of the usual crypto algorithms like AES and RSA are too complex to use on embedded devices, lightweight versions have been implemented. Both have their benefits and drawbacks. Symmetric cryptography requires less processing power and the short key length takes up less memory. On the other hand, to enable communication between nodes each pair of nodes must share the same private key. In large networks this effects scalability since it increases the necessary memory requirements for key storage. It also provides a new problem of secure key distribution. While there are ways to do this, they all increase the network complexity. Asymmetric cryptography algorithms are safer in comparison and do not have any scalability or safe key distribution problems. But they do require more processing power and longer keys take up more memory. Most of the research in the last 5 years points to Elliptic Curve Cryptosystems [13] as having most potential. They allows for strong public key encryption with relatively short keys. When implementing any solution, the characteristics of the network play a major role [14].

It is important to note that all security protocols are designed with the idea that any node can be compromised at any time. The sink is usually considered the biggest security threat in a network and for this reason generally better protected. Security protocols increase the complexity of a network in the form of message overhead, longer start up time and processing constraints. Security frameworks and libraries do exist and are mostly open-source. Lastly, when talking about security threats to the communication protocol layer, one must remember that for the time bring all attacks will most likely be from the inside. To execute a successful attack, the attacker must have solid knowledge of: computer security, wireless communication and embedded networks. In conclusion, the biggest security threats are people who design the network.

V. NETWORK LAYER ATTACKS

Network layer attacks are logical attacks which focus on disrupting of putting stress on the network control mechanisms. They include flooding attacks, attacks on mitigated lower layer threats and routing attacks.

A. *Flooding attack*

Flooding attacks are a form of denial of service. Instead of obscuring communication between nodes, fake or malicious nodes try to join the network. Every time a node requests to join a network, the closest nearby node will try to respond by sending back a signal. If the fake node never joins the network but keeps sending more requests to join, the process will just continue in turn draining the node of all its power. This can be countered by authentication algorithms. It requires a trusted third side to first identify nodes and then allow them to connect to the network. This would mean that the fake node will just be ignored once identified. Implementing a trusted third side increases the complexity of the network in the number of messages send. Depending on the implementation it does not increase the processing time since that can be done outside the network.

B. *Attacks on mitigated lower layer threats*

Attacks on mitigated lower layer threats are new security threats which derive from eliminating other threats via implementation of a network layer solution for them. A simple example of this is: using a group coordinator to prevent node capture. While this removes one threat, it now makes some node much more valuable to attack. There is no clear solution or general recommendation in such cases. Every security measure has its own weakness and making a system secure only depends on our notion of what degree or risk are we willing to accept. As stated before, these cases are very dependent of the type and characteristics of a network as are the recommended solutions.

C. *Routing attacks*

Routing attacks are cases where the flow of the data in the network is in some way altered to either hamper the network or provide benefit to the attacker. They require the attacker to already have control of one or more nodes within a network or being able to join the network with his own nodes. Such attacks focus on one of two things. The attacker will try to gain access to data from as many nodes as possible by routing the messages by his nodes or, he will focus on making sure that useful messages are not sent to the sink or required node. There are five types of attacks: selective forwarding, misdirection, sinkholes, wormholes and Sybil attack.

1) *Selective forwarding*

Selective forwarding is an attack where a node will only send some of the received messages while dropping others. Since all networks expect that a certain amount of messages will not be successfully sent and received, this attack could go on undetected. A simple example of this is when nodes are grouped to decide on the correct sensory reading. By only sending some of the information it is easy to influence the outcome of the group reading, while at the same time remaining undetected outside of the group. Selective forwarding is the most basic type of attack. It can be used by itself, by simply blocking all messages or it can be used as a tool to execute more complex attacks.

2) *Misdirection*

Misdirection is a form of attack where messages are intentionally sent to the wrong node. In some networks this could cause a change in the routing path. Depending on the configuration of the network, if a node were to continuously receive messages from its neighbor, it could come to the conclusion that some other part of the network was compromised and that a new routing path is needed. By doing so, network traffic could easily be forwarded using an already compromised node. Similarly to selective forwarding, misdirection can be its own goal or can be used to start a specific attack.

3) *Sinkhole attack*

Sinkhole attacks are groups of methods used to divert traffic to a specific node. Misdirection and selective forwarding would be such methods. Once all the network traffic is moving to a single node, it is up the attacker whether to use the opportunity to listen in or to disrupt communication.

4) *Wormhole attack*

Wormhole attacks are a clever way to use or create sinkhole attacks. For example, an attacker adds two nodes to a network which consider themselves neighbors. One of nodes is very close to the sink and the other is far away but surrounded by other nodes. What happens next is that the traffic will be forwarded via the newly created wormhole. If we look at the routing table of the compromised node in the middle of all the other nodes, then that node will be the closest connection to the sink in the area. This will make all the surrounding nodes start forwarding messages to that node. The attacker can than easily obtain all the sent messages of those node, since they are being forwarded between two nodes that he controls. Sinkhole and wormhole attacks can be used to disrupt the work of the network, but are mainly used to gather data without the attacker being detected.

5) *Sybil attack*

A Sybil attack is a disruptive attack in which one node presents itself as a number of nodes at the same time. This

allows the attacker to make his node very attractive to other nodes. In turn easily creating a sinkhole or disrupting the routing tables of nearby node.

Defending against routing attacks can be done in three ways. The first layer of defense is a good authentication system. If the attacker cannot add nodes to the network, he is forces to gain control of existing ones, which is a lot harder. Making an optimal routing system is the second step. Routing should not only be designed to be efficient but also very robust. Using different disjoint paths and algorithms which do not reconfigure, unless a multi node consensus is made, greatly improve security. The last part is to use redundancy. The success of an attack on a network is usually based on the fact: "can an attacker take over the critical number of nodes, within a given time, without being detected". Knowing this and the fact that nodes are relatively cheap, the security of a network can be greatly improved just be adding more nodes. Each of these steps greatly adds to the complexity or cost of the network.

VI. DETECTING ROUTING ATTACKS BY USING A MOBILE SINK

We propose a possible 4th option to defend against routing attacks by using a partially mobile sink node with the intent of better intruder detection. The idea comes from using a sometimes overlooked characteristic of WSNs: mobility. While a fully mobile wireless sensor network has even more security problems, because of even greater constraints, a partially mobile network may be able to achieve a balanced solution.

This method would be used in an aggregation type network. The network should be densely populated by nodes. The number of nodes should be around the point where randomly removing 20% of the nodes in the network would not cause any serious communication interruption. From the point of view of a single node it would mean that every node would have at least 3 other nodes within communication range Because of the high number of nodes, such networks are much more susceptible to sinkhole and wormhole attacks. By using a specific algorithm and sensors in the sink it should be possible to do a highly effective diagnosis of the network. Such a method in itself would not cause a significant message overhead but would require a larger number of control messages to be sent. This would allow for networks to have a lot more optimized routing tables without the need to plan redundant pathways. There are also certain applications, depending on the algorithm, to allow for location privacy. We plan on conducting more research in this field to determine if benefits gained from such a method would outweigh the disadvantages of using a mobile network. Also, we would like develop more models where such a method is useful, apart from intruder detection. Since mobile and partially mobile wireless sensor networks are a relatively new area, we believe that any research into this area will be greatly beneficial to finding an optimal solution to the current WSN security problems.

VII. CONCLUSION

Wireless sensor networks still face a large number of security problems due to limited memory, low processing strength and bandwidth issues. Nevertheless researchers have in the last 5 years slowly made progress by adapting and applying already known security methods to suit the possibilities of an embedded system. Network layer algorithms can detect and prevent lower level attacks like node corruption and node capture. Asymmetric cryptography is now a feasible option by using Elliptic Curve Cryptosystems. And better understanding of secure routing has increased network accessibility during attacks. We will continue working in the area of network layer security by experimenting with partially mobile sinks. In doing so, we want to determine if such methods can put less overall stress on routing algorithms, taking into account the added complexity of mobile wireless sensor networks, while providing the same level of security and intruder detection.

{marko.misic, djordje.djurdjevic, mvt}@etf.bg.ac.rs

Abstract – Central Processing Units (CPUs) are task-parallel, latency-oriented processors, while Graphics Processing Units (GPUs) are data-parallel, throughput oriented processors. Besides their traditional use as graphics coprocessors, the GPUs have been used in recent years for general purpose computations, too. Rapid development of graphics hardware led to an extensive use in both scientific and commercial applications. Numerous papers report high speedups in various domains. This paper presents an effort to bring GPU computing closer to programmers and wider community of users. GPU computing is explored through NVIDIA Compute Unified Device Architecture (CUDA) that is currently the most mature application programming interface (API) for general purpose computation on GPUs.

I. INTRODUCTION

From their beginning, graphics processing units (GPUs) have been used for specialized, intensive computations in the domain of computer graphics. Rendering of 3D graphics is a good example of highly intensive parallel computation. It includes computations for both geometry (vertices) and rasterization (pixels). Strong pressure from the fast growing gaming industry and the demand for fast, high definition graphics led to constant innovation and evolution of GPUs towards highly parallel, programmable processors with lots of GFLOPS and high throughput.

Central processing units (CPUs) are task-parallel, latency-oriented processors with transistors devoted to caching and sophisticated flow control. On the contrary, GPUs are data-parallel and throughput-oriented processors that hide relatively expensive global memory accesses with extensive use of parallel threads. Contemporary CPUs could be considered as *multicore* processors, since they need only several threads to fulfill their full capacity, while GPUs are *manycore* processors that need thousands of threads for their full use. The GPUs could be seen as coprocessing units to the CPUs, which are suitable for problems that exhibit high regularity and arithmetic intensity. Typically, the sequential parts of the program are executed on CPU, while the compute-intensive parts are offloaded to GPU to speedup the whole process.

The GPUs are found in many applications. At the very beginning, they were used mostly in academia, but since they brought significant speedups in several domains they were adopted from wider research community. GPUs are nowadays used in computational physics, computational chemistry, life sciences, signal processing, as well as finances, oil and gas exploration, etc.

This work has been partially funded by the Ministry of Education and Science of the Republic of Serbia (III44009 and TR32039). The authors gratefully acknowledge the financial support.

The rest of the paper is organized as follows. The second section presents a short history of modern GPUs, and gives a further discussion on General-Purpose computation on Graphic Processing Units (GPGPU). The third section presents an overview of the Compute Unified Device Architecture (CUDA) that exploits GPU computing power for general purpose computation. The fourth section concentrates on the issues related to CUDA program execution and performance optimization. The fifth section of the paper gives a brief discussion on application domains suitable for GPU computing and presents some programming primitives and common algorithms. Sixth section reveals some of the experiences and lessons learned by the authors of this paper. The final section briefly concludes the paper and discusses the future trends of GPU computing.

II. TOWARDS GENERAL PURPOSE COMPUTATION ON GPUS

In the early stages of their existence, the GPUs have been fixed-function processors used primarily for 3D graphics rendering. The entire execution was built around graphics pipeline that was made configurable to some extent, but not programmable [1]. GPUs were specialized to render a screen picture through several steps, as shown in Figure 1. About the same time, 3D graphics application programming interfaces (APIs) became popular, notably OpenGL and Direct3D component of Microsoft DirectX. They exposed several programmable features to the programmers. The direction towards more programmable processors was driven by the fact that programmers wanted to create more complex visual effects on the screen than those provided by the fixed-function graphics hardware. In these early days of the GPU programming, the programmer had to send the short programs to the GPU, by calling API functions. These programs processed graphic primitives.

A. Graphics hardware evolution

In graphics pipelines, certain stages do a great deal of floating-point arithmetic on completely independent data, such as transforming the positions of triangle vertices or generating pixel colors. This data independence, as the dominant application characteristics, is the key difference between the design assumption for GPUs and CPUs [1]. It allows a usage of a substantial hardware parallelism to process the bulks of data.

The first attempts to make the commercially available graphics processors more programmable exposed the vertex shader programmability, in NVIDIA GeForce 3 [2]. Further development provided programmability of the pixel shaders and full 32-bit floating point arithmetic

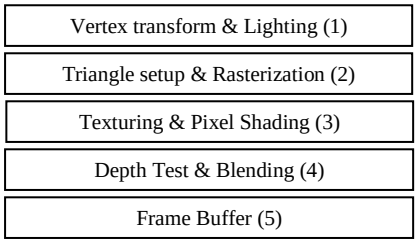

Figure 1. Fixed-function graphics pipeline

support. The vertex and pixel shader programs essentially define the behavior of the stages 1 and 3 in the fixed graphics pipeline (Figure 1.), respectively. Also, as an important improvement, texture lookups were made possible from the vertex shader stage. This development could be seen as a trend to unify the functionalities of different graphics pipeline stages, since they essentially required the same processing capabilities. ATI Xenos GPU, made for the gaming console Xbox 360, was the first to allow the vertex and pixel shaders to execute on the same (non-specialized) processor. This unified approach proved to be successful and was consequently adopted in modern GPUs.

Also, graphics rendering made an impact to memory architecture of the GPUs. Typically, input data are processed only once during one stage and accessed in a strictly coherent way. Rendering algorithms usually access contiguous memory locations simultaneously which allows efficient memory bandwidth utilization. The GPU memory is organized in banks that allow simultaneous access to neighboring memory locations. The GPU memory architecture is built to emphasize bandwidth over latency, bringing more than 100 GB/s in recent GPUs. Whereas the CPU die area is dominated by cache memories, GPUs are dominated by floating-point datapath and fixed-function logic [1], thus efficiently hiding latency with massive parallelism.

On the other hand, the GPU memory organization had a very restricted memory access policy. Since the output data of the shader programs are pixels, they have predefined positions on the screen (and thus in the frame buffer). The output address of a pixel is always determined before the pixel is processed and the processor cannot change the output location of a pixel, so the pixel processors were incapable of memory "scatter" operations [3]. For several generations, GPUs lacked an efficient way to do the scatter operation, e.g. to write to a calculated (arbitrary) memory address.

B. Software support for general purpose computation

In the early stages of the GPU development, some researchers noticed the computational power of those processors and tried to use that power to solve general, compute-intensive problems. Because typical graphics scenes consist of primitives defined with fewer vertices than the number of pixels on modern displays, the programmable stage with the highest arithmetic rates in modern GPU pipeline is the pixel shader stage. Therefore, a typical GPU program used the pixel processor as the computation engine for the general-purpose computation on the GPU [3].

However, that was a challenging process, since it involved the usage of the graphics-oriented APIs, such as OpenGL or Direct3D, to launch a computation. Besides learning the basics of the API, one also needed to express a general-computation problem in the sense of graphics primitives and write the appropriate shader program. Again, output data needed to be converted from a pixel form, stored in a frame buffer, to data meaningful to the programmer. A very good example of such a programming model for the common problem of fluid simulation is found in [4]. Since OpenGL and Direct3D are primarily intended for graphics usage, no common features, like user data types or bitwise operators, were available. Also, attempts to do GPU programming were hindered by lack of dedicated tool chain – proper compiler support, debugging and profiling tools, and libraries.

Despite this quite awkward way of programming in the beginning, researchers demonstrated usefulness of GPUs for solving general-purpose problems in various domains. Papers [3] and [4] reported significant speedups in the domains of computational physics (fluid dynamics, game physics, etc.), computational biology (protein folding), and image processing (magnetic resonance imaging). Many more examples can be found in [3], including a survey of suitable programming techniques and data structures for GPU programming.

C. GPU computing era

The first fully unified GPU, NVIDIA GeForce 8800, brought an array of unified processors that execute logical graphics pipeline with the support of some fixed-function logic. Vertex shading, geometry shading, and pixel shading were executed on the same array of processors and used the same pool of resources. This design pursued much better workload balance, since different stages need different amount of resources during their execution that could be dynamically allocated.

The GeForce 8800 was also the first GPU to use scalar thread processors rather than vector processors [5]. It brought a wider instruction set to support C and other general-purpose languages, including integer and IEEE 754 floating-point arithmetic. Also, the GeForce 8800 eliminated memory access restrictions and provided load and store memory access instructions with byte addressing. It provided new hardware and instructions to support parallel computation, communication, and synchronization. Contemporary NVIDIA GPUs are programmed through simple C language extension and corresponding application programming interface or, more recently, through OpenCL API.

Similarly to NVIDIA, ATI (now AMD) also introduced unified shader architecture with Radeon 2000/3000 series of processors. Unlike NVIDIA that exposed GPU programmability through C language extension, AMD firstly exposed programmability through low-level programming interface, called Close-To-Metal that did not gain much success. Its successor, Stream SDK, included an open-source Brook+ language for GPGPU. In a more recent development, AMD switched to fully supported OpenCL, as a main platform to program their GPUs [6].

III. CUDA OVERVIEW

CUDA (Compute Unified Device Architecture) is a parallel computer architecture developed by NVIDIA, which came as a result of a need to simplify the use of GPUs for non-graphics applications. CUDA exposed a generic parallel programming model in a multithreaded environment, with support for synchronization, atomic operations, and eased memory access. Programmers do not need to use graphics API anymore to execute non-graphics computation.

A. *Programming model*

Essentially, the processing units of the GPU follow a single program multiple-data (SPMD) programming model, since many elements are processed in parallel using the same program. Processing elements (threads) can read data from a shared global memory (a "gather" operation) and write back to arbitrary locations in shared global memory ("scatter" operation). Generally, threads execute the same code that is inherent to SIMD execution model. However, since threads could follow different execution paths through branching in the same program, that leads to more general SPMD programming model.

Programs on the CUDA platform are executed in co-processing mode. Typically, the application consists of two parts. Sequential parts of the application are executed on the CPU (host) that is responsible for data management, memory transfers, and the GPU execution configuration. Compute-intensive, parallel parts of the code are executed on the GPU (device) as special functions (kernels) that are called by the CPU.

A kernel is executed by a large number of lightweight threads that run on the processing units called streaming multiprocessors (SMs). Every streaming multiprocessor is a SIMD processor, currently consisting of up to 32 scalar processors. Threads are organized in blocks executed on a single multiprocessor, and kernel execution is organized as a grid of thread blocks, as shown in Figure 2. Thread blocks executed on the same SM share the available resources, such as registers and shared memory. Depending on the commercial target niche, modern GPUs have from 2 up to 32 streaming multiprocessors. Due to this organization of thread execution, a kernel scales very well across any number of parallel processors. Efficient threading management in GPUs allows applications to expose a much larger amount of parallelism than available through hardware execution resources, with little or no penalty [1]. A compiled CUDA program executes on any size GPU automatically using more parallelism on GPUs with more processor cores and threads [5].

The number of threads in a block, and the number of blocks in a grid are specified through execution configuration of the kernel. Both block and grid could be multidimensional (1D, 2D and 3D) to support different memory access patterns. Every thread has a unique thread index within a block, and every block has a unique identifier within a grid. Threads can access those identifiers and dimensionality through special, built-in variables. Typically, every thread uses its own indices to make branching decisions, and to simplify memory addressing, when processing multidimensional data.

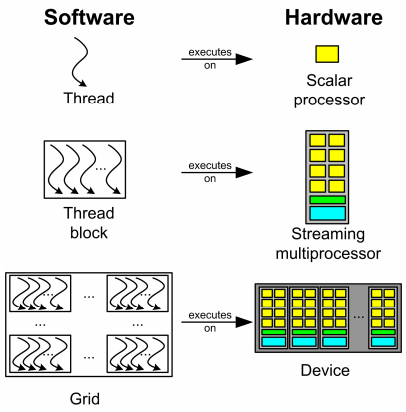

Figure 2. CUDA execution model

CUDA provides a way to synchronize threads in the same block using the barrier synchronization primitive. However, threads in different thread blocks cannot cooperate, since they could be executed on different streaming multiprocessors. Global synchronization is possible only through repeated kernel calls, which is one of the inherent limitations of manycore architectures.

B. *Memory hierarchy*

CUDA offers specific memory hierarchy to support fast, parallel execution. Threads have access to registers, local memory, shared memory, constant memory, texture memory, and global memory. All threads have access to slow, global device memory (DRAM). However, access to global memory is slow (approx. 200 cycles), in comparison to other memories, so other smaller memories could be used for temporary storage and reuse of data.. Every thread has an exclusive access to given (allocated) registers and local memory. Although private to the thread, local memory is off-chip. Hence, access to local memory is as expensive as access to global memory [7]. Threads in a block could share data through per-block shared memory. Shared memory could be seen as a user-managed cache (scratchpad) memory as it could be accessed very fast (3-4 cycles). The programmer is responsible to bring the data to and move it from the shared memory. Also, threads can access constant memory, that is read-only and cached, and texture memory using special hardware units.

IV. PERFORMANCE CONSIDERATIONS

Although it is not difficult to write a correct CUDA program that can run on any CUDA device, performance can vary greatly depending on the resource constraints of the particular device architecture. So, performance concerned programmers still need to be aware of them to make a good use of a contemporary hardware.

A. *Thread scheduling and execution*

Logically, threads are executed in thread batches, called thread blocks. Physically, however, every thread block is executed on a SM in 32-thread units called warps. Threads in a block are partitioned into warps based on their indices. Consecutive threads could be considered to reside in the same warp. Threads in a block can execute in any order relatively to each other, so the synchronization is needed to avoid race conditions.

Warps are used as an execution optimization technique to hide latency of the long-latency operations, such as global memory accesses or floating-point operations. Every SM implements zero-overhead warp scheduling policy. The selection of warps ready for execution does not impose any additional time, so the waiting time of warp instructions is hidden by executing instructions from other warps.

All threads in a warp execute the same instruction when selected for execution. This SIMD style of execution works well when all threads in a warp execute the same path. But, since GPUs allow threads to follow different execution paths, a problem arises when threads within a warp diverge. In those situations, the hardware sequentially executes both control paths for all threads in a warp and thus creates a performance penalty. The programmer is responsible to structure the code in a way to avoid incoherent branching. A good example of how *if-then-else* construct is executed on SM can be found in [1], and a good survey on flow control mechanisms used in GPUs in [3].

B. Memory access

Global memory access is slow (approx. 200 cycles) in comparison with access to other memories in the hierarchy. But, since GPU applications process vast bulks of data, global memory accesses should be carefully considered to reach the peak bandwidth available on the GPUs. Also, to achieve high bandwidth utilization, the GPU memory is organized in banks. On NVIDIA Tesla GPU architecture, the memory is divided in 16 banks. Each bank can serve one memory request per cycle. To allow simultaneous accesses, consecutive memory locations are located in consecutive memory banks. Multiple simultaneous accesses to the same bank result in a bank conflict and conflicting accesses are then serialized.

When accessing global memory, peak bandwidth utilization is achieved when all threads in a half of the warp access consecutive memory locations. Memory accesses are then combined into a single memory transaction and data are delivered at high rates. This technique is called memory coalescing. Essentially, programmers should organize memory accesses in a way that follows those favorable patterns.

C. Shared memory

In order to achieve high performance on the GPUs, many computations should be done between two global memory accesses. To achieve better reuse of data and improve arithmetic intensity, threads can cooperate through per block shared memory. Usually, data set is partitioned into subsets that fit into the shared memory. Each thread block loads the subset from the global memory to shared memory and then performs computation on the given elements. Threads use shared memory for temporary storage and cooperation. Each thread block then writes the results from shared memory to global memory. Loading and storing of data should be done in a coherent way to exploit memory coalescing. The above described technique is often referred to as “tiling” technique for data processing on the GPUs.

D. Resource limitations

Every streaming multiprocessor in the GPU has a limited set of execution resources such as registers, thread block slots, thread slots, and shared memory. These resources are dynamically partitioned among threads during the execution. One can run a smaller number of threads that require many registers each or a large number of threads that require few registers. Dynamic partitioning of the resources gives more flexibility to compilers and programmers, but can also result in underutilization of resources, and thus performance degradation. More one this topic can be found in [1] and [7].

E. Streams

Beside the massive data parallelism through the kernel execution, CUDA offers one more way to overlap tasks. CUDA exposes the concept of streams which presents a kind of a task-parallelism between CPU and the GPU [8]. Stream represents a queue of GPU operations such as memory copies and kernel launches that get executed in a specific order. Streams can help to accelerate GPU applications by overlapping kernel execution and memory copies between the CPU and the GPU. More on concurrent execution between CPU and GPU can be found in [8] and [9].

V. APPLICATION DOMAINS

The GPU performance and computational power offer a lot for particular classes of applications. A very good survey of characteristics that application needs to satisfy to be successfully mapped for GPU execution could be found in [4].

First, parallelism should be substantial. The GPU utilization depends on a high degree of parallelism in the workload. The GPU also needs a substantial workload to hide memory latency, so computational requirements should be large. Thus, high throughput is more important than latency in GPU systems. Number of numeric computations performed per memory transaction should be an order of magnitude higher in order to preserve arithmetic intensity. On the other hand, execution divergence should be avoided as much as possible. Since threads are run in batches, if threads within a batch diverge, there is a penalty in prolonged execution. Finally, bandwidth utilization has to be sustainable. The GPUs have high peak bandwidth utilization to and from their onboard memory. But, for applications, such as sorting, that have a low computation to bandwidth ratio, it is of great importance to maximize coherent memory accesses.

A. GPU primitives

GPU programming exposes a different programming model and paradigm than traditional, sequential programming. That requires the programming constructs familiar to parallel supercomputer users, but often new to ordinary programmers reared on sequential machines or loosely coupled clusters [4]. New primitives and data structures, suitable for GPU execution, gained interest from research community [10]. Also, manycore architecture of the contemporary GPUs revived several old ideas, such those that emphasize parallel prefix sum

(scan) operation [11] and sorting networks [12]. Sorting operation is the well-studied operation on GPUs and it is discussed in section VI.A.

There are several proprietary and open-source libraries that implement common algorithms on the GPU. Those include FFT algorithms (cuFFT), BLAS library (cuBLAS), pseudorandom-number generation (cuRAND), and CUDPP (CUDA Data Parallel Primitives) library that implements primitives like scan, sorting, and reduction [13]. Also, several projects try to provide higher level interfaces for CUDA programming. Thrust project [14] provides high-level, object-oriented API for GPU programming. The GMAC project implements an asymmetric distributed shared memory model to be used by CUDA programs [15]. That model allows CPU code to access data hosted in GPU memory.

B. *GPU applications*

Numerous papers reported speedups in various application domains. Papers [3] and [4] give a fine survey on those applications. The GPU accelerated applications are used in computational physics, computational chemistry, life sciences, medical imagining, mathematics (linear algebra, differential equations solvers), computer vision, signal and image processing and many more.

Notable scientific applications that benefited from GPU acceleration are NAMD [16] and VMD [17] molecular dynamics software, developed at University of Illinois, Urbana-Champaign, AMBER molecular mechanics software [18], and Folding@home project (protein folding) at the Stanford University [19]. Also, numerous commercial software packages are accelerated using GPUs, such as MathWorks MATLAB, Adobe Photoshop, and many more.

VI. CASE STUDY

This section outlines the experiences of the authors of this paper with the GPU accelerated applications. It shortly describes sorting on the GPU, as one of the frequently used primitives in the GPU computing, and domino-tiling, the CUDA accelerated algorithm for conforming the triangular mesh generation..

A. *Sorting on the GPUs*

Sorting operations are the important parts in modern applications, since these operations are used to optimize the search and merge activities, to produce the human-readable form of data, etc. The GPU-based sorting implementations attracted the researchers with several papers reporting significant speedups in quicksort [20], merge sort and radix sort algorithms [21]. Sorting operations are bandwidth consuming and access data in irregular patterns, so they heavily depend on efficient shared memory utilization. The authors of this paper shared a similar experience with the GPU sorting algorithms as in [22] and [23], where they conducted a performance comparison of those algorithms in the controlled test environment. The results shown in those papers suggest that the GPU implementations of the common sorting algorithms are 3 to 5 times faster

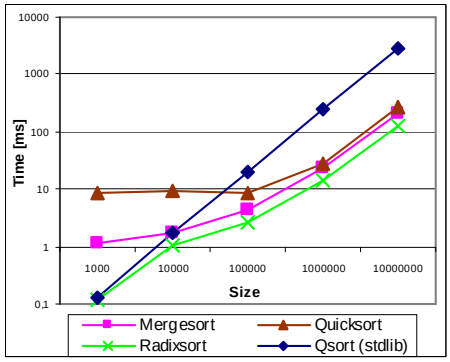

Figure 3. Performance comparison of the GPU sorting algorithms and CPU sequential (qsort) algorithm

compared to the same algorithms implemented on the shared memory and message passing platforms.

Figure 3. shows an interesting comparison between the GPU sorting algorithms and standard C library sort function, *qsort*. Typically, the GPU implementations outperform the sequential *qsort*, except for arrays under 10k elements. The GPU kernel calls need some preparatory steps, so there is an amount of parallel overhead involved in the execution of every GPU algorithm. That time prevails in the overall execution time for smaller arrays, while it is amortized for larger arrays.

B. *Domino tiling*

One of the authors experienced the advantage in using CUDA to accelerate computations in the domain of computer graphics. The GPU accelerated fast conforming triangular mesh construction for rendering changeable height fields, dubbed Domino Tiling (DT) is presented in [24]. DT constructs a triangular mesh by deploying predefined mesh patterns (consisting of many triangles) so that the adjacent patterns seamlessly match, similarly to a domino game. One pattern is assigned to each height field patch (a small square portion of the height field), as an approximation of the fully accurate mesh. Mesh construction involves the visibility culling and level-of-details computation for each patch.

The speed comparison results are presented in Figure 4. The experiments were carried out on two different height fields (Puget Sound and Utah) for three different sizes, from 4K×4K points to 16K×16K points. The times given for CUDA implementation include the transfer time

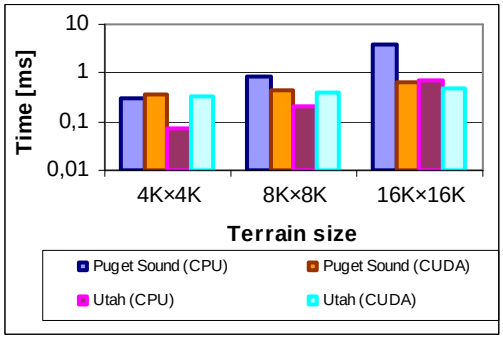

Figure 4. Performance comparison of the sequential (CPU) and CUDA (GPU) implementation of the Domino Tiling algorithm.

of the computation results, from GPU memory to CPU memory. For smaller terrain sizes, the CPU implementation is faster, especially in the case of the Utah dataset for the size 4K×4K. As the terrain size increases, the CUDA implementation takes the upper hand, and becomes significantly faster (Puget Sound dataset, 16K×16K). The reason for this effect is the inevitable overhead in invocation of several CUDA kernels and the final data transfer. The impact of the overhead diminishes as the height field grows larger. The speed comparison also shows that the CUDA implementation scales much better with the height field size than the CPU implementation. The CUDA implementation shows a sublinear increase in the computation time, while the computation time roughly quadruples in the CPU implementation.

VII. Conclusion and Future Trends

The paper presents an introduction to the general purpose GPU computing and focuses on CUDA, the most mature programming interface in the domain. Performance considerations and an overview of current application domains are given.

With the introduction of Fermi GPU architecture in 2010, NVIDIA has already taken steps to improve GPU performance and robustness. Fermi architecture relaxed some resource utilization constraints, improved flow control, introduced L2 caches, and unified GPU memory space [5]. Introduction of L2 caches largely relaxed memory coalescing constraints, since they provide hardware level support. Also, multi-GPU connection has been improved, with the support of direct memory transfers.

In the API domain, it is expected to see wider adoption of OpenCL in the programming community, since it is supported by major competitors in the field. OpenCL brings parallel computation to a broader set of devices, so there are still performance tuning considerations, but they are expected to be alleviated with maturity of OpenCL drivers for different architectures.

The fate of coprocessors in commodity computers, such as floating-point coprocessors, has been to end up into the chipset or onto the microprocessor [4]. Although the GPUs resisted that trend with constant performance improvements, potential performance increase could motivate such hybrid solutions. Hybrid CPU/GPU approaches could be seen in foreseeable future, with all major competitors announcing their new, hybrid architectures. Intel has already launched new SandyBridge architecture with integrated GPU and announced new MIC (Many Integrated Cores) architecture. AMD has the similar approach for mobile devices, called Fusion. Also, NVIDIA presented their new, research approach for heterogeneous computing, called Echelon [25].

In the future, it is expected that GPU architectures will evolve to further broaden application domains and to become more agile and better suited to handle arbitrary control flow and data access patterns. With many applications that benefited from GPU acceleration, GPU computing will become increasingly important. Since, sequential processors do not scale anymore at satisfactory rates, programmers need to use parallelism offered by the manycore architectures for an increased performance required to deliver more value to the end users.

Abstract - The infrastructure set up by the EDGI EU FP7 project contains Desktop Grid (DG) sites (BOINC or XtremWeb) performing the execution of jobs coming from gLite, ARC or Unicore type service grids. The infrastructure contains an Application Repository (AR) as a central service storing all relevant information for applications. This AR is also the key to the gateways of the Desktop Grid sites, since enabling the execution of a given application on a DG site can be performed through the AR. The entire infrastructure has a monitoring system developed to collect statistical information about job execution. However, validating the information in the AR and testing job execution against the DG site was still missing. In order to evaluate the operation of the EDGI infrastructure, a new service has been designed and prototyped. This service collects all relevant information and submits jobs to Desktop Grids to gather data about their current state. This data can then be used by monitoring agents. A reporting webpage for the administrators is implemented. We will also show how reporting can be integrated with the Nagios system.

I. INTRODUCTION

A. The EDGI Infrastructure

The FP7 European Desktop Grid Initiative (EDGI) [1] project has created an infrastructure which integrates Desktop Grids (DG) with Service Grids (SG) in order to support European Grid Initiative (EGI) and National Grid Initiative (NGI) user communities to run applications which require large number of CPUs and cores. EDGI went beyond existing Distributed Computing Infrastructures (DCI) that typically incorporate cluster Grids and supercomputer Grids. It extended these grids with public and private Desktop Grids and Clouds. The project integrates software components of different cloud middleware (OpenNebula and OpenStack), Service Grid middleware (ARC, gLite, Unicore), and Desktop Grid middleware (BOINC[4] and XWHEP[7]) into SG→DG→Cloud platform for service provision. The EDGI infrastructure connects Service Grids with private, public and volunteer DG resources through the SG→DG bridge [2]. The project also provides access to Clouds from Desktop Grids via the DG→Cloud bridge to get additional resources for DG systems if the applications have QoS requirements that could not be satisfied by the available DG resources. EDGI deployed the production EDGI infrastructure that integrates ARC-, gLite- and Unicore-based Service Grids with Desktop Grids based on the EDGI bridge middleware. This production infrastructure also enables the dynamic and on-demand extensions of the connected Desktop Grids with Cloud resources. As a result, e-scientists

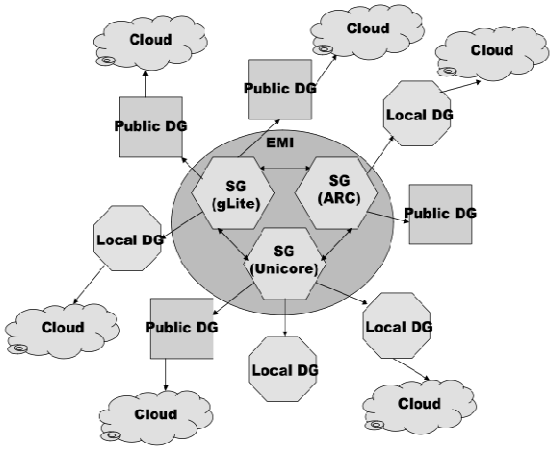

Figure 1. The EDGI Eco-system

can benefit of the flexible and versatile eco-system provided by the EDGI project (Fig. 1).

The EDGI Infrastructure (Fig. 2) contains the EDGI Portal, the EDGI Application Repository, the SG→DG bridge and the Desktop and Service Grid resources. There are five major user types of the EDGI Infrastructure: E-scientists, Application Developers, Application Validators, Desktop Grid Administrators and Repository Administrator. The EDGI Portal is the GUI to submit and monitor applications, and retrieve and display results. The EDGI Application Repository stores the non-validated (private) and validated (public) applications. E-scientists can browse and search the repository in order to find applications they want to execute.

B. The EDGI Application Repository

The security models of Desktop and Service Grids are significantly different. While Service Grids trust the users and identify them by unique certificates, Desktop Grid systems trust the applications instead. As a result, only trusted and validated applications can run on DG systems. If users of a Service Grid infrastructure want to utilize

Desktop Grid resources then the applications should be trusted and pre-deployed on the supporting DG systems. This requires the application validation and uploading them into an application repository where both users and DG system administrators can access them. Moreover, the bridging mechanism from an SG to a DG system should always check that the application submitted via the bridge available and validated in the repository and identical to the submitted executable. The EDGI project designed and implemented the EDGI Application Repository, which is based on the EDGeS Application Repository (EDGeS AR), to support the full life-cycle of application validation, deployment and usage. As the focus of EDGeS was the creation of the production bridging mechanisms, the EDGeS Application Repository only provides the minimum set of required functionalities to bridge Service Grids to the target DG systems.

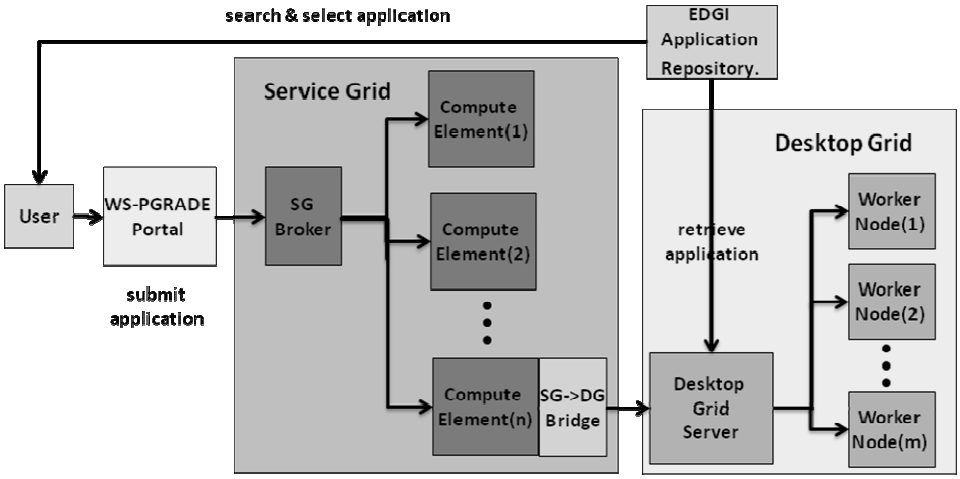

Figure 2. The EDGI Infrastructure

The repository is used by six actors, i.e. the six user types given above and the Modified Computing Elements. E-scientists are end-users who want to run applications on the EDGI Infrastructure. They want to search and browse the repository to find validated applications which they want to execute. Application Developers are computer scientists are familiar with infrastructure where the applications are executed. They elaborate these applications to enable e-scientists to run their applications on the EDGI infrastructure. To achieve it they have to be able to develop applications with their implementations and configurations. After implementing and uploading the applications into the repository they mark them as non-validated and they should notify Application Validators. If the developer modifies a validated application, then a new non-validated version is automatically created which should be validated. After significant updates, the developer could depreciate previous application versions after successful validation. Application Validators are also computer scientists who test applications created by application developers. They should find non-validated applications submitted by application developers, download packages and sample inputs and attempt to run the applications. After successful validation they give feedback about the applications and make them available for the Repository Administrator by marking them as validated. Desktop Grid Administrators manage Desktop Grid resources. They can search the repository and download validated application packages for deployment. They can allow users to use available resources by installing applications on the EDGI Infrastructure. Repository Administrator manages the repository, i.e. he/she handles users (registering/deleting and modifying their data).

The EDGI AR stores three types of components: applications, implementations and configurations. Application represents an application i.e. software. It describes the inputs and outputs and explains what the application does. However it does not actually contain any files necessary to run the application itself because there can be different implementations available e.g. for different operating systems. Implementation defines an implementation of an application. It strictly follows the input and output definitions of the application and implements the functionality given in the application description. It contains or references (via e.g. URLs) all the files and also holds other data/metadata necessary to run the application on a given platform. An implementation goes through a validation process and is eventually deployed on a resource. Implementations have a list of sites where they are or can be installed. Configuration describes in which Desktop Grid and/or Service Grid the implementation can be executed. It also stores files such as input and sample files, which are needed to run the applications.

C. Consistency and Availability

An application registered in the Application Repository may be assigned to multiple backend grids. The AR and each of these grids may pertain to different domains of authority; they are managed by different members of the project. The consistency among them is not managed automatically; it must be enforced on a higher level, by pro-

ject leaders. However, there were not any tools for easy administration.

We have developed a component which collects data from individual grids and compares it against the contents of the Application Repository. This information can be used by project managers and members to maintain consistency throughout the EDGI infrastructure.

If an application is consistently registered and deployed, it may still be unusable due to availability problems of the underlying grid. Automatic black-box testing of the infrastructure is necessary to maintain availability. The component that tests the infrastructure can use the consistency information to skip tests which will not succeed anyway.

II. Evaluating Consistency

Our goal is to support maintenance of consistency between the Application Repository and each backend Desktop grid in the infrastructure. Backend grids are independent of each other; consistency between two – or generally, over any set – is undefined.

It is important to note, that Clouds are not included in the testing process. Clouds in the EDGI infrastructure are "only" used to provide additional dedicated resources for the various Desktop Grid backends. In our testing mechanism we consider the Desktop Grid as one powerful resource, but not going down to the level of individual resources. The correct operation and accessibility of a Cloud is realized by standard monitoring tools shipped with the cloud middleware.

First, we gather information from the backend grids. A modified computing element accesses the underlying grid through a bridge. Each bridge may be connected to multiple backend grids. Bridges do not support brokering incoming jobs; instead, the client must specify the target grid. For this, each bridge maintains multiple queues, each queue being associated with a single backend grid. Therefore, we can state that a target grid can be identified with a (Bridge, Queue) pair. Each grid may support multiple applications, whose list can be queried from the associated bridge. The structure of the information in a bridge is shown on Fig. 3. Gathering information from all known bridges results in a set containing (Bridge, Queue, AppName) triplets.

Grids to be evaluated and their associated (Bridge, Queue) pairs must be configured manually; there is no component which provides this information. Bridges have a web-service interface; the bridge can be identified by this service's URL. The list of applications supported by a given Bridge/Queue pair can be queried through its WS-interface. Thus, data is generated in the following way:

1) (Grid name, (Bridge URL, Queue)) associations must be configured.
2) For each grid configured, the list of applications is queried from the bridge.
3) The result is a set of (Grid name, Bridge URL, Queue, AppName) tuples.

After extracting information from grids, we need to acquire information stored in the Application Repository. The structure of the information in the AR – the relevant part, thereof – is shown on Fig. 4. Each application – identified by its (canonical) name – may have multiple Implementations and each Implementation may have multiple GridIDs associated with it. A GridID is a tuple specifying the name of the supporting grid, and optionally, a bridge-specific name (GridAppName) for the application. The same application may have different names in different grids. If the GridID does not specify one, the GridAppName is the same as the canonical name. Normalizing this structure, we get a set of (Application, (Grid, GridAppName)) associations.

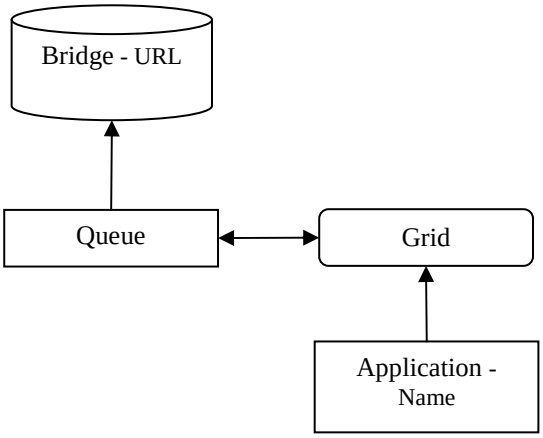

Figure 3. Bridge Information

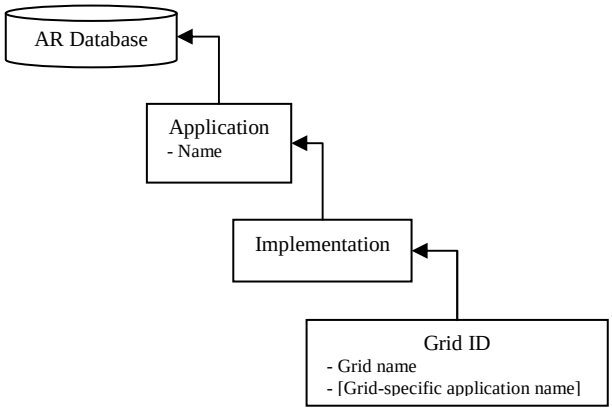

Figure 4. AR Information

We have to integrate these database schemas. The flattened schemas resulting from bridge and AR queries and the associations between them are shown on Fig. 5. Assuming that the two sets of information are consistent, they can be combined in a single dataset. However, sometimes AR and grid information is inconsistent due to infrastructural or administrative errors. The following inconsistencies and problems can be identified:

1) The AR is referencing a bridge that is unknown (i.e. not configured for evaluation).

2) The AR is referencing a bridge that is unavailable.

3) The AR is referencing an application which is not registered in the associated grid.

4) A bridge reports an application which is not referenced in the AR.

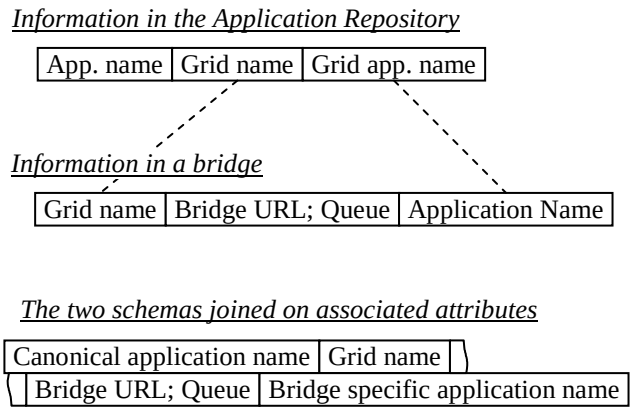

Figure 5. AR-Grid Information Associations

Identifying these problems and presenting them in a user-friendly way helps administrators and project leaders maintaining the infrastructure:

1) If the AR references a grid unknown to the testing system, the administrator can check the AR for a typo or may configure the new grid in the testing system.

2) System administrators can check firewall settings and service state if the bridge is reported to be unreachable.

3) If the AR references an application which is missing from the grid, if the grid administrator forgot to register that application, the test system can prompt him to correct the error.

4) Usually, it's not a problem, if an application is registered in a grid but is not registered in the AR; it may be the grid owners' own application. However, seeing this, the project leader may ask the grid administrators to make this application public by registering it in the AR, so other users can benefit from it.

Since installing our prototype system, the consistency and availability of the EDGI infrastructure has improved greatly. This system made it much easier to maintain the infrastructure and to coordinate participants of the project. Furthermore, the consistency information can be used to optimize the infrastructure testing by skipping tests which would not possibly succeed. A possible presentation of the results can be seen on Fig.6. The rows of the table represent applications, the columns represent grids. Each cell shows where that specific application is registered: AR/DG/AR+DG. Unreachable bridges, unknown grids and inconsistencies are highlighted.

III. TESTING THE INFRASTRUCTURE

In the EDGI infrastructure, multiple smaller infrastructures are being integrated. While monitoring backend grids individually [6] is necessary, assessing availability of the whole integrated system cannot be simply done by testing its components. To measure the availability of the EDGI infrastructure, we have developed a simple component, which submits pre-configured test-jobs to the system periodically. This component does nothing else; interpreting the results is the responsibility of a higher layer.

Before submitting test-jobs, the result of the consistency analysis is checked. If a certain test-job is expected to fail because of a misconfiguration in the system or infrastructure outage, the test can be omitted. If the job may finish successfully, it is submitted and the results are recorded.

For each (Grid, Application) pair a test case can be defined. If a given application in a given grid is found to be consistently registered, both in the AR and the grid, the associated test can be executed. Practically, this means that each item of the joint schema (see Fig. 5.) may be associated with a test case. Each test is a black box for the testing system. For input, the joint information is provided. The output is expected to be a status code and – in case of an error – a message. Also, the test must have a timeout defined for that application. The testing system is entirely indifferent of the mechanism implemented in a test. It may be a gLite submission script or a direct submission to the bridge; the commands in the script may even be executed remotely on a UI machine. In the prototype, we implemented direct bridge submission from remote UI machine.

The test system will submit new tests periodically, and query the state of pending tests from time to time. In our prototype system, we submit two tests for each application every hour and query pending tests every thirty minutes. If a test does not finish before the defined timeout, the test is cancelled and reported to be failed.

1) Displaying the Results

Interpreting the results is not trivial; particularly in case of volunteer desktop grids. Volunteer desktop grids need much higher timeout for jobs than institutional desktop grids. While an institutional DG can finish jobs in a short time (i.e. within an hour), a volunteer DG may need almost a month or even more to provide results. For example, in case of the EDGIDemo DG, each hour two tests are submitted, and most of the time the results arrive before the next test submission. In contrast, the SZDG [8] volunteer DG has a thirty day timeout for jobs, which – depending on the load of the DG – usually proves to be too little.

High timeout for tests means high lag of the information provided by the testing system. Suppose we start testing a grid in which we have a 30 day timeout. In the worst-case scenario, we need to wait a month before we can decide, whether a particular test has failed. This means that whenever the infrastructure fails, the fact of failure can only be established 30 days after the actual event. Lowering the timeout would result in higher failure rates, as tests would be less likely to finish in time. Anoth-

er way is to monitor the current output of the infrastructure. That is, because we provide a continuous load on the infrastructure, we can expect continuous output rate if we assume a uniform lead time of jobs. The problem here is the opposite of the previous. Whenever the infrastructure fails, we are notified almost immediately. However, when the system has recovered from a failure and testing has

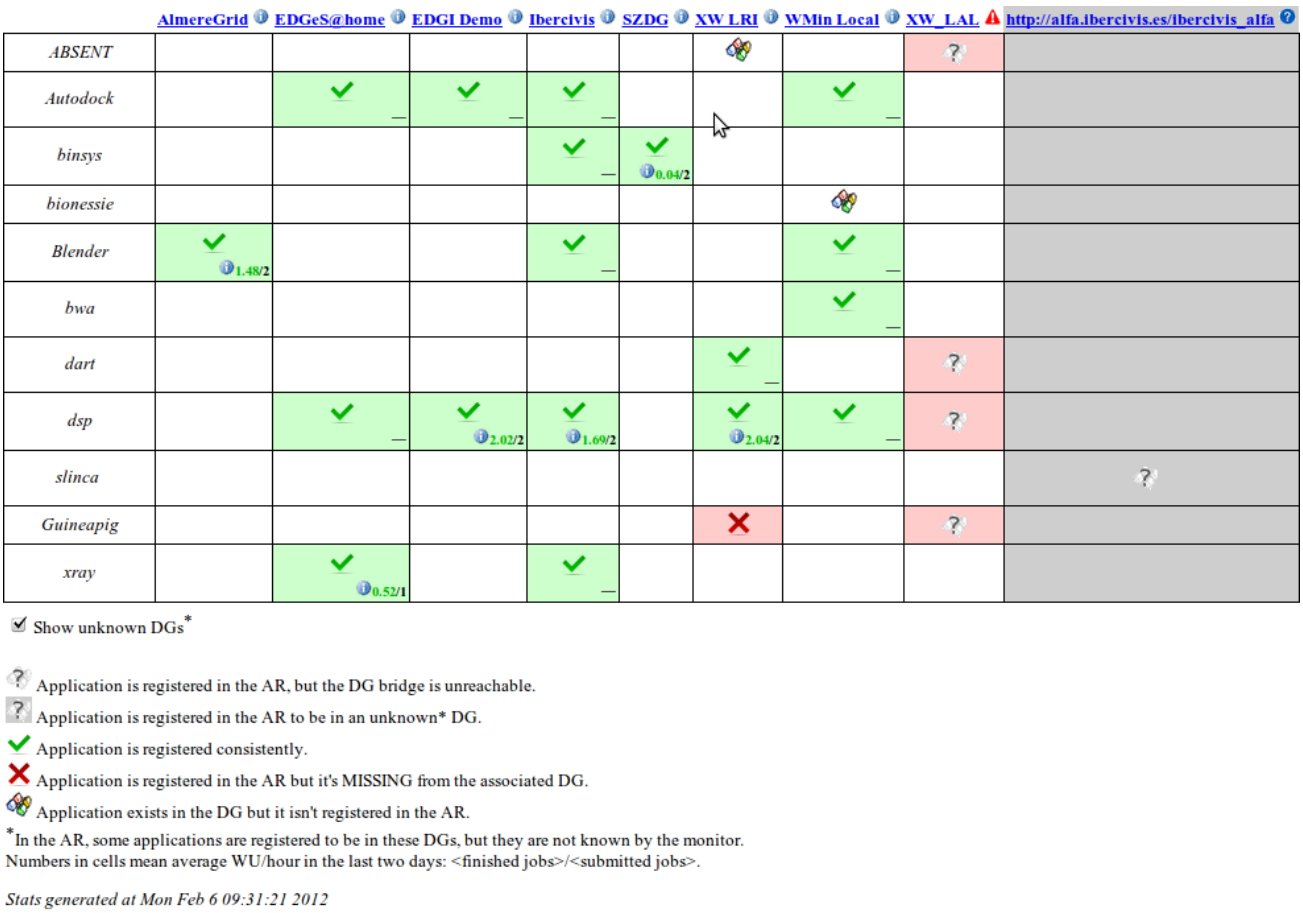

Figure 6. Web Page Based on Consistency and Test Data

begun, we need to wait until the first tests start to finish. In the aspect of maintenance, this is a much better choice; even so because smaller outages will not affect the results at all. However, if we want to provide availability information to users, this method has the disadvantage of misinforming them while the system is "bootstrapping"; showing them the infrastructure is unreliable, while it is actually up and running.

In the prototype, we used the latter method. We show for each tested application, how many test jobs have finished in an hour on average through a certain timeframe. This is still problematic since the moving average will flatten the series a little, but with a well-chosen timeframe size, this information can still be useful. Also, volunteer and institutional DGs will produce series with different characteristics. In our experience, submitting two tests each hour, an institutional DG will finish around two jobs by hour on average, while a volunteer will finish around 0.04. The numbers produced by volunteer DGs can be explained with their (very) high load. Usually, the load in a volunteer DG is *kept* high, and because the workunits are processed in a FIFO fashion, the test jobs will not be executed before the test system cancels them due to timeout. We conjecture that introducing job-priorities and submitting test jobs with high priority would correct this anomaly.

Because of the nature of the data, we have not created a system which interprets the data; instead we show the processed data on a web page, and let the administrators draw conclusions from it. A web page is shown on Fig.6. Each tested application has a number pair in its cell, where the first number is the hourly average number of finished tests from the last two days, and the second is the number of tests submitted each hour.

2) *Using Test Results in Nagios*

Nagios [5] is a powerful, scalable and flexible monitoring framework that enables to identify IT infrastructure

problems. It is free software, licensed under the terms of the GNU General Public License version 2. Nagios already have lots of plugins for checking host resources (disk usage, processor load, etc.) and network services (HTTP, ICMP, FTP, SSH, etc.) because of its flexibility. Plugins can be written in many shell and program languages. We designed and implemented a plugin which can extend our monitoring system with alerting and alternate visualization back end. This plugin checks data generated by the test system periodically. It investigates the number of finished and failed jobs per day and sends alarms via e-mail for the administrators when expected conditions are not met.

IV. CONLUSION

The EDGI infrastructure was designed to promote access to high capacity desktop grid resources. While we have most certainly reached this goal, the monitoring of the system was still unreliable. We have designed an automatic testing system, which

- Monitors consistency among the components of the EDGI infrastructure
- Creates availability data by regular submission of test-jobs to each grid

This information can be used in various ways. We have implemented two applications using this data: a web page, which helps project administrators to manage project participants; and a Nagios plugin which alerts system administrators on infrastructure failures.

Although automatic interpretation of the data is far from trivial, the UI provided by the system is sufficient for an administrator to maintain the EDGI infrastructure. Since the prototype system has been deployed, many anomalies and errors have been corrected; for example typos and misconfigurations in the Application Repository, missing applications from participating desktop grids, or—in case of most newly joined desktop grids—unopened firewalls. Also, the system allows us to notice outages in the infrastructure with small delay, thus these problems can be addressed quickly.

V. FUTURE WORK

Although our prototype system proved to be useful as-is, there are several things we can further improve.

The Application Repository may act as a grid information repository. Storing (Grid, Bridge URL, Queue) associations in the AR – in a central location, that is – would decrease the possibility of inconsistencies in the infrastructure. Also, manual configuration of the testing system would be unnecessary.

We will investigate the possibilities of high-priority job submission. We conjecture that doing so would make volunteer and institutional desktop grid results comparable; therefore, we could interpret the data automatically, creating an even more reliable monitoring system.

ACKNOWLEDGMENT

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement no 261556 (EDGI)

Abstract - The Hadoop Distributed File System (HDFS) is one of the important subprojects of the Apache Hadoop project that allows the distributed processing and fast access to large data sets on distributed storage platforms. The HDFS is normally installed on a cluster of computers. When the cluster becomes undersized, one commonly used possibility is to scale the cluster by adding new computers and storage devices. Another possibility, not exploited so far, is to resort for resources on another computer cluster. In this paper we present a multicluster HDFS installation extended across two clusters, with different operating systems, connected over the Internet. The specific networking parameters and HDFS configuration parameters, needed for a multicluster installation, are presented. We have benchmarked a single and dual cluster installation with the same networking and configuration parameters. The benchmark results indicate that multicluster HDFS provide increased storage area, however, the data manipulation speed is limited by the bandwidth of communication channel that connects both clusters.

I. INTRODUCTION

The big data applications on distributed storage systems gain importance in different fields of applications [1-3]. The Apache Hadoop [4] is an open source software project sponsored by the Apache Software Foundation (http://www.apache.org). The Apache Hadoop software library allows the distributed processing of large data sets across clusters of computers using a simple programming model. It is designed to scale up from a single server to thousands of machines, each offering local computation and storage [5]. Rather than rely just on hardware to deliver high-availability, the HDFS library is designed to detect and handle failures at the application layer. As a result, the HDFS is a highly-available service that can be installed on commercially available clusters of computers, which have not been built with any special care for minimizing the failure rate.

Hadoop encompasses multiple subprojects:

- Hadoop Common: The common utilities that support the other Hadoop subprojects,
- Hadoop Distributed File System (HDFS): A distributed file system that provides high-throughput access to application data, and
- Hadoop MapReduce: A software framework for distributed processing of large data sets on compute clusters.

The HDFS is a file system designed for storing very large files with streaming data access patterns, running on clusters of commodity hardware. There are Hadoop clusters running today that store petabytes of data [6].

Since the Hadoop is designed to run on commodity hardware, when a Hadoop cluster becomes undersized, one commonly used possibility is to scale the cluster by adding new computers and storage devices. Another possibility, not exploited so far, is to resort for resources on another computer cluster. The latter paradigm is sometimes called "scaling out".

The Hadoop cluster nodes are organized in a master-worker pattern. There is one namenode that has the master role and there is a number of datanodes, which are the slaves. The namenode manages the file system namespace. It maintains the file system tree and the metadata for all the files and directories in the tree. All this information is stored on a disk in the form of two files: the namespace image and the edit log. The namenode is configured to know the addresses of the datanodes that store the blocks for a given file.

A Hadoop client accesses the HDFS file system by communicating with the namenode and datanodes. The user code does not need to know about the namenode and datanode functionality because of the POSIX-like [7] file system interface between the Hadoop client and the system.

The datanodes store or retrieve blocks when a request comes from the Headoop client or the namenode. The datanodes also report periodically to the namenode and send it lists of blocks that they are storing. Without the namenode, the file system cannot be used. In a case of an error on the machine running the namenode, all the files on the file system could be lost because there is no alternative way to reconstruct the files from the blocks on the datanodes. For this reason, it is important to make the namenode resilient to failures.

To evaluate the feasibility and effectiveness of HDFS, we have made a test HDFS installation. The installation consists of a single namenode and five datanodes inside a cluster residing at Jožef Stefan Institute (JSI), and one additional datanode on a cluster accessible over the Internet and located at Turboinštitut d.d. (TI). Hence, the installed system spreads over two clusters and is therefore called multicluster HDFS installation. It is to be distinguished from the notion of a hybrid cloud, which represents a collaboration of a private and a public cloud.

In the rest of the paper the architecture of the HDFS multicluster is described together with the description of HDFS configuration parameters. For the purpose of

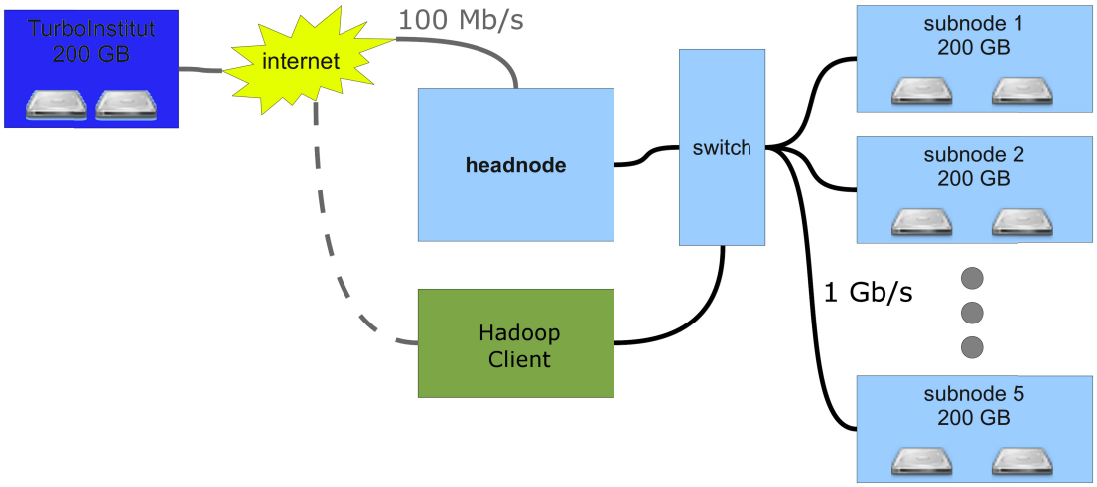

Figure 1. Multicluster storage system arhitecture

testing and analyzing the HDFS performances, we have constructed a set of benchmark programs, described in Section III. The benchmark results are presented and commented in Section IV. Our paper concludes with a summary of achieved results and some directions for the future work.

II. METHODS

A. System arhitecture

The experimental HDFS installation has the following configuration:

- Master node, the multicluster's headnode, which is the headnode of the JSI cluster, is running:
  - namenode
  - jobtracker,
- each of subnodes 1 till 5 at the JSI cluster and the subnode at the TI cluster are running:
  - datanode
  - tasktrecker.

The namenode and the jobtracker are running on the same machine, as it is usually acceptable for small clusters, i.e., on clusters with up to 10 nodes [8].

Each node on the JSI cluster has a single 500 GB data disk with the rotation speed of 7200 rpm. Only the head node is equipped with the RAID. The local network in the cluster is 1 Gb/s, while the external internet connection bandwidth is 100 Mb/s. Each JSI cluster node has 6 GB of RAM and Intel(R) Xeon(R) E5520 @ 2.27 GHz processor with four cores.

The TI cluster node has two Intel(R) Xeon(R) L5520 @ 2.27GHz processors, each with four cores, and 24 GB of RAM. The TI cluster node has a single 260 GB data disk.

On each of the available disks a partition of 200 GB is allocated for the utilization by the HDFS. The partitions are formatted with the ext4 file system.

This work was done under the competence center CLoud Assisted ServiceS (KC CLASS), founded by the Slovenian Ministry of Education Science and Technology, and the European Fund for Regional Development.

The JSI cluster nodes run under Ubuntu Server operating system, while the TI cluster node runs under SUSE Linux operating system. The described multicluster system architecture is shown in Fig. 1.

B. HDFS Configuration

Since Hadoop scripts rely on SSH to perform cluster-wide operations, SSH needs to be setup to allow password-less login for the Hadoop user from all machines in the multicluster system. This is achieved by generating one RSA [9] public/private key pair shared across the multicluster.

The software configuration of Hadoop cluster consists of an environment configuration for the execution of Hadoop daemons, and their parameters configuration. The Hadoop configuration parameters are stored in various configuration files located in the *conf* directory of the Hadoop distribution. Each Hadoop node in the cluster has its own set of configuration files. It is up to the administrator to ensure that they are kept synchronized across the whole system. The Hadoop provides a rudimentary facility for synchronizing configuration by using rsync [10].

The list of all datanodes is in the *slaves* configuration file containing IP addresses (on the local network) of the machines where the datanodes and tasktrackers should run. In our multicluster architecture the list also contains the IP address of the TI node, which can be accessed over the Virtual Private Network (VPN). It is obligatory to use the VPN address of machines in another cluster, since these are the only addresses visible to the namenode machine.

The parameter JAVA_HOME located in *hadoop-env.sh* configuration file specifies the location of the Java implementation to be used. Setting the value in hadoop-env.sh on all the machines in the multicluster is preferable because it ensures that the whole cluster is using the same version of Java.

The parameter fs.default.name, located in the *core-site.xml* configuration file, is normally (in plain cluster installation) set to the IP address or the name of the

namenode machine. It is an HDFS file system URI that defines the hostname and the port that the namenode's RPC server runs on. The default port is 8020. However, in the multicluster installation, the machine (or machines) located outside the namenode's cluster do not "see" the namenodes's IP on the local network. Therefore, it is necessary to use the namenodes VPN address, which is seen by all machines in the multicluster. Note that when a property is marked as final it is protected from being overridden by job configurations.

The parameters dfs.name.dir in the *hdfs-site.xml* configuration file specifies a list of directories where the namenode stores persistent files system metadata, while dfs.data.dir parameter in the same file specifies a list of directories where the datanode stores its blocks. In the multicluster installation, the nodes in the main cluster may need different dfs.data.dir parameter value than the nodes on the remote cluster. Because the remote cluster may be using different operating system and may be controlled by different administrator, the directory configured for the main cluster does not have to exist on the remote cluster. Therefore, in our case, two versions of the *hdfs-site.xml* configuration file are maintained: one for the nodes on the main JSI cluster and other for the node on the remote TI cluster. All the other parameters are left default. Note that the default replication factor is three.

The same holds for parameters mapred.local.dir and mapred.system.dir from the *mapred-site.xml* configuration file, which specify the location of local temporary storage for intermediate data and working files that are produced during a MapReduce job [11], and a directory where the shared files for the MapReduce tasks files can be stored. Hence, for our multicluster, two versions of the *mapred-site.xml* configuration file are maintained.

III. PROGRAMS FOR TESTING

We have developed scripts for benchmarking of the Hadoop deployment.

```
#!/bin/bash
if [[ "$1" == "rm" ]]; then
    /usr/local/hadoop-0.20.203.0/bin/hadoop dfs -fs
    hdfs://ninestein/ -rm /user/guest/$2
elif [[ "$1" == "ls" ]]; then
    /usr/local/hadoop-0.20.203.0/bin/hadoop dfs -fs
    hdfs://ninestein/ -ls
elif [[ "$1" == "up" ]]; then
    /usr/local/hadoop-0.20.203.0/bin/hadoop dfs -fs
    hdfs://ninestein/ -copyFromLocal $2  /user/guest
elif [[ "$1" == "down" ]]; then
    rm $2 &>>/dev/null
    /usr/local/hadoop-0.20.203.0/bin/hadoop dfs -fs
    hdfs://ninestein/ -copyToLocal /user/guest/$2 .
fi
```

File 1. hadoop.sh

The file *hadoop.sh* (File 1.) is a script that does the file operations. The first parameter of the script is therequested file operation: deletion, listing, copying to HDFS, or copying from HDFS. The second parameter is the file name.

The script *hadoop_testing.sh* does the actual benchmarking (File 2). It is accessing files of different sizes, copying them to or from the HDFS, and measuring the time needed for the operation. It uses the script *hadoop.sh* for the actual operations with files. Each copy operation is repeated 5 times to obtain an average operation time.

```
#!/bin/bash
# writing
for i in 1 10 100 1000 10000 100000 1000000
2000000 3000000; do
    #fill the cache
    dd if=benchmark/$i.file of=/dev/null
    &>>/dev/null
    echo -n "$i, "
    for ((j=0; j<5; j++));
    do
        #writing time
        time=$(/usr/bin/time -f %e ./hadoop.sh up
        benchmark/$i.file 2>&1)
        echo -n "`echo $time | awk '{print $1}'`, "
        if [[ "$j" != "4" ]]; then
            ./hadoop.sh rm $i.file &>>/dev/null
        fi
    done
done
# reading
for i in 1 10 100 1000 10000 100000 1000000

IV. BENCHMARK RESULTS

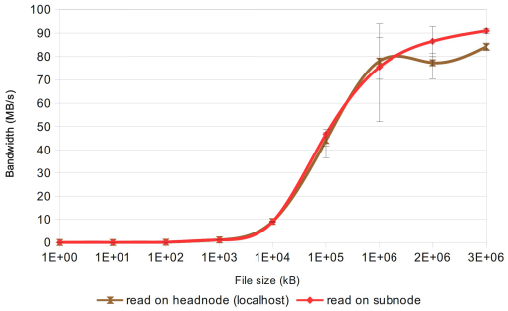

Figure 2. Read bandwidth as a function of file size (JSI cluster)

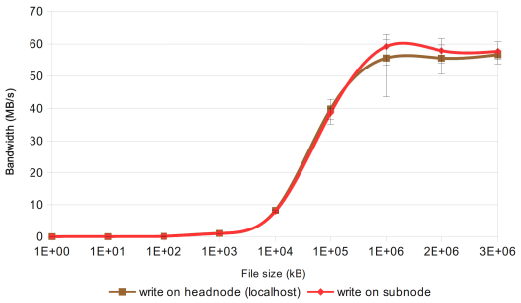

Figure 3. Write bandwidth as a function of file size (JSI cluster)

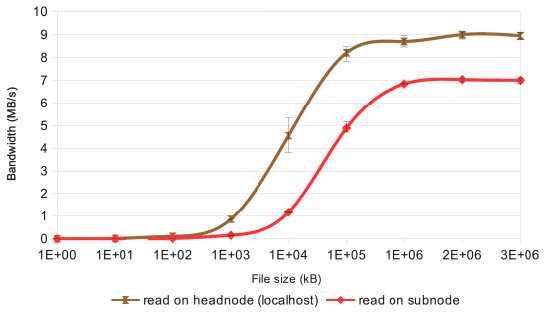

Figure 4. Read bandwidth as a function of file size (multicluster)

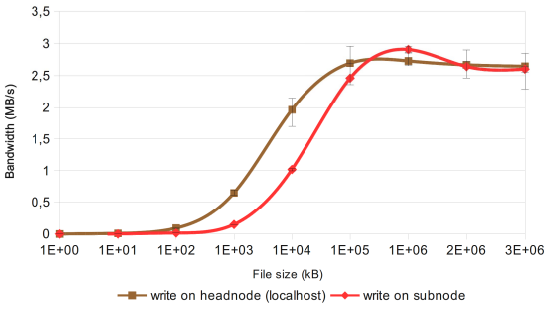

Figure 5. Write bandwidth as a function of file size (multicluster)

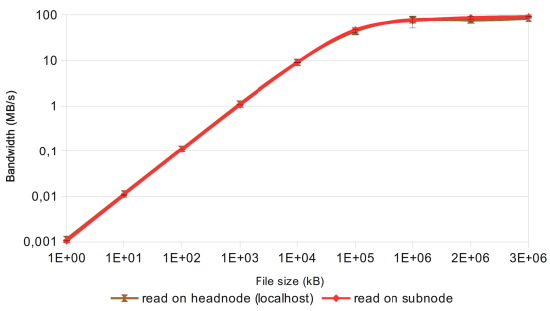

Figure 6. Read bandwidth as a function of file size in logarithmic scale (JSI cluster)

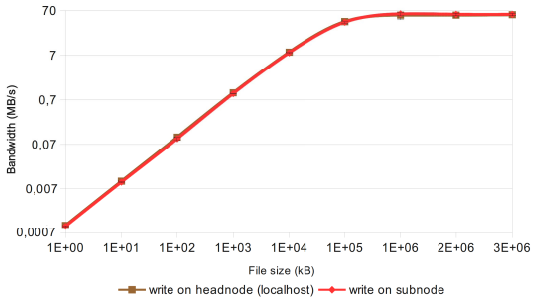

Figure 7. Write bandwidth as a function of file size in logarithmic scale (JSI cluster)

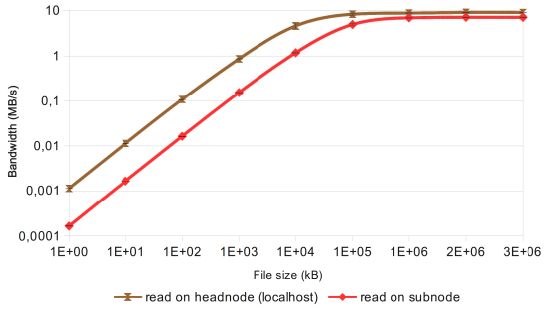

Figure 8. Read bandwidth as a function of file size in logarithmic scale (multicluster)

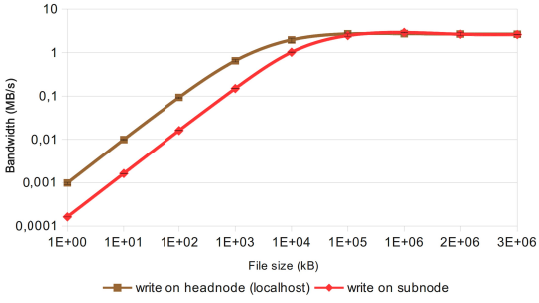

Figure 9. Writing bandwidth as a function of file size in logarithmic scale (multicluster)

The read and write operations have been conducted from the headnode, located on the JSI cluster, and from a JSI cluster's subnode.

The read and write bandwidths were tested for file sizes form 1 kB up to $3 \cdot 10^6$ kB. Any experiment has been repeated five times for each file size. The whiskers on the graphs (Figures 2 - 9) represent value ranges (max-min) for the five cases, while the mark represents the average value of each set of experiments.

Fig. 2 and 3 show the read and write performances obtained on the JSI cluster only (the TI node was not a part of the test system). Fig. 4 and Fig. 5 depict the read and write performances obtained on the interconnected JSI and TI clusters (multicluster). Figures 6 – 9 show the same results but in the logarithmic scale on the y axis to provide better inside into the performances for smaller files.

We see from Fig. 2 and Fig. 3, obtained from the JSI cluster, that the read and write bandwidths are almost the same regardless of the node from which the operations are conducted. The maximal write bandwidth is approximately 35 % lower than the maximal read bandwidth.

In the multicluster case (Fig. 4 and Fig. 5), the read bandwidth is significantly higher for the headnode. This behavior can be expected because, if the read operations are performed form a subnode, there is a possibility for a delay due to the communication with the headnode. The maximal write bandwidth is almost equal for the headnode and the subnode. However, for file sizes of 10^6 kB the write bandwidth is higher if write operations are performed from the subnode. We could explain such a behavior with eventually available storage data buffers.

The logarithmic scale of y-axis in Fig. 6 to Fig. 9. discovers that the bandwidths grow linearly up to file sizes of 10^5 kB. We can observe that the manipulation with the smaller files is constantly 10 times slower on the multicluster system. For files larger than 10^5 kB the bandwidths reach their maximal values and remain quite stable. Again, there is approximately tenfold difference in the bandwidth in favor of the system with IJS cluster only. This can be expected because the data from the TI cluster are accessed through the 100 Mb/s Internet connection, which is approximately ten times slower than the JSI cluster network (see Fig 1.).

V. CONLUSION

We have presented the steps and configurations needed for deploying the Hadoop on a multicluster. We further tested the installation with a series of benchmarks, developed for this purpose. The multicluster paradigm enables a HDFS cluster to be scaled out to physical machines that are accessible over the internet. Such an approach may decrease the investments if an existing storage system becomes occasionally undersized.

We have performed a series of benchmarks on the JSI Hadoop cluster and on the multicluster constituted by joining a storage node from the TI cluster. Benchmark results indicate that the read and write bandwidths drop significantly with joining the TI node. One obvious reason for such a behavior is slow communication line between the clusters, but this drawback can be easily improved by introducing a faster interconnection channel. Further investigation is needed to identify the Hadoop implementtation properties that influence the fall of performance. We suspect that a smarter organization of data items on a higher abstraction level, e.g., user location aware approach, could, in most cases, alleviate this problem.

However, the drop in read and write bandwidths does not necessary imply the same drop in performances of MapReduce jobs, because Hadoop does its best to run the Map tasks on nodes where input data reside in the HDFS, because of build-in "data locality optimization" principle. The Reduce tasks, usually, don't possess the advantage of data locality as the input to a single reduce task is most often the output from all mappers. Further tests with MapReduce jobs are therefore needed to investigate the influence of the multicluster architecture on the Hadoop MapReduce performances.

The multicluster storage, presented in this paper, was built from computing nodes of two clusters on different geographical positions, with different hardware platforms and different operating systems, which confirms that a multicluster Hadoop on heterogeneous clusters is a viable option. The read and write performances of HDFS, if critical for a multicluster application, have to be improved, e.g., by increasing the communication speed of the inter-cluster connection.

ACKNOWLEDGMENT

The authors are grateful to Turboinštitut d.d. for granting a full access to their storage and computational resources at Ljubljana Supercomputing Center - LSC ADRIA.

Abstract - Today's applications, especially those in the scientific community, deal with an ever growing amount of data. Among the problems that arise from this explosion of data are how to organize the data so that the information about how the data was produced is not lost, how to ensure repeatability of calculations, how to automate calculations, and how to save computational and storage resources. The storage is currently a passive component that neither imposes any rules on data organization nor helps with associating a calculation with its result. We thus introduce AbacusFS – an integrated storage and computational platform which interacts with the file system and connects the calculations and the storage. Users and applications see it as a normal file system; however, the semantics are changed for files that are results of calculations done with the platform. When such a file is open for reading, AbacusFS first re-generates it if the input files used in the calculation have been modified. Alternatively, result files can be virtual, i.e. not stored anywhere but rather re-generated on every read access.

I. INTRODUCTION

Today's applications, especially those in the scientific community, deal with an ever growing amount of data [1]. Major problem in using these applications is tracking changes of the intermediate data. Users of these applications want to focus mainly on the final results and do not want to be considered with intermediate results, changes in the files, parameters, versions etc. They would like more automation and repeatability.

Using storage efficiently and economically is a major problem because of the increasing amount of data and the fact that advances in storage, particularly storage speed, lag behind advances in CPU speed. Depending on available CPUs, available storage devices and their location, it may be faster or cheaper to re-generate (re-calculate) the data whenever it is needed rather than storing everything. In HPC a lot of data is long term archived on tape. Re-calculating the data could sometimes prove more economical than getting it from tape. Furthermore, from the energy consumption point of view it may be optimal to start the calculation only when the results are needed instead of when the user has requested (because of the differences in costs in different times, i.e. computing costs at night might be lower than at day).

There are thus two significant and related problems: 1) data organization and 2) performance and efficiency. In order to solve the problems of data organization, reproducibility and automation of calculations we need to make calculations aware of changes in input files, parameters, software versions etc. The result that is needed by the user could then be re-calculated if something has changed. In the case of workflows of multiple calculations, changes to any initial or intermediate file could trigger re-calculation of the dependent part of the workflow. One of the problems that may arise here is the problem of nondeterministic applications in which the results might slightly vary in the last digits. For now we do not tackle these problems, rather our focus is on the deterministic applications. The performance and efficiency problem is correlated with the first one. Some intermediate files in the calculations are perhaps changed very often and it may be better to re-calculate them every time rather to store them permanently. Others may be accessed frequently but rarely changed, so they are better stored permanently or even replicated on multiple storage nodes.

To tackle these problems we propose AbacusFS, a solution that intends to change the paradigm in which we observe storage, or more specifically, file systems. Applications currently just use the storage without any interaction or integration between the two. Current storage systems neither impose any rules on data organization nor help with associating a calculation with its result. The basic idea of the solution presented in this paper is to make file systems application-aware in order to improve the efficiency of storage use, shorten the time to obtain calculation results, and automate certain repetitive tasks for the user.

A. Related work

There are two important research fields which relate to our solution: virtualizing processes with file systems and building file systems in user space.

One of the recent solutions in this area is the concept of a desynchronizing file system or DesyncFS [2]. DesyncFS deals with the problems of heterogeneity in supercomputers which imposes problems with scientific applications with a lot of internal dependencies. Due to different performances of the hardware the applications run at the speed of the least powerful processor. In order for these applications to perform better they need to be desynchronized.

In the traditional relationship between application and file system, control resides in the application and it calls into the file system as needed for storage. This can be described as a push-pull relationship. The file system is passive and the application actively pushes and pulls data. A desynchronizing file system inverts this relationship, making the file system active and the application passive [2].

Solution which we propose deals with different problem but it also tries to change the relationship between storage and applications. One other difference is that in order to use DesyncFS a user has to adapt the applications for it where in the case of our solution there is no need for any changes in the applications.

Linux has a long tradition of user-space file systems (e.g. Network File System (NFS) [4] was implemented this way for quite some time). User-space file systems are not widely used mostly because of performance and security reasons [5]. However there are advantages in building a file system in user space: an ability to build and modify the file system without changing the kernel; shaping the file system to the needs of the user with the ability to use functions from the user space. One of the most important projects in that area is FUSE [6]. File System in User Space (FUSE) is a loadable kernel module for Unix-like computer operating systems that lets non-privileged users create their own file systems without editing kernel code. This is achieved by running file system code in user space while the FUSE module provides only a "bridge" to the actual kernel interfaces. FUSE is particularly useful for writing virtual file systems. Unlike traditional file systems that essentially save data to and retrieve data from disk, virtual file systems do not actually store data themselves. They act as a view or translation of an existing file system or storage device.

One of the ever growing problems in the scientific community is managing and running workflows. Provenance in the context of workflows, both for the data they derive and for their specification, is an essential component to allow for result reproducibility, sharing, and knowledge re-use in the scientific community [7]. Scientific workflows has become an important area of research within workflow platforms and environments. Workflows are supported in the AbacusFS and in the future we would like to extend that feature to add more workflow management. Some important platforms and frameworks in this area are: Taverna [8], Askalon [9] and Trident [10].

The concept of using file systems to store dynamic (non-persistant data) is present for some time. The Linux proc file system [11] has been around from 1984 and it is used widely Today. The device file system (devfs) [12] is also widely used for presenting device files. It provides a powerful new device menagement mechanism for Linux.

II. DESIGN AND ARCHITECTURE

A. General design

We introduce an integrated file system/computational platform that connects calculations and storage. This platform is currently implemented on a single machine with plans to extend it to distributed systems (cluster/grid/cloud), where the advantages of such a solution will be more evident. The users of the platform will be able to deploy scientific calculations without worrying about re-calculation every time they make some changes in the calculation parameters or input files. They will also be able to see how each file was produced.

Let us illustrate the usage of the platform with an use case. Whenever a user runs some calculation, the full command-line and other information is stored as metadata associated with the calculation's output file(s). Then, each time one of the output files is open for reading, it is first checked whether it is up-to-date, i.e. whether the input files have changed. If they have changed, the file is automatically re-generated by running the original command again and file access is allowed only after the re-calculation has finished. All existing command-line applications can be used without modifications, except for the applications that write to pre-existing files. The fact that input files can also be results of previous calculations does not pose any problem, so workflows are supported natively.

Running calculation when the command is issued and then re-calculating whenever the results are needed and any inputs have changed is not always optimal. For example, in next generation of supercomputing, moving data from the storage to the computing nodes may be more time and resource consuming than recomputing this information because we may have more available idle CPU power. A part of our platform is thus a decision-making process that can take into account parameters such as file size, number of read accesses, number of re-calculations of the file, and a user-assigned file importance. In the future we plan to refine the decision-making process and with it add more parameters.

B. Architecture overview

AbacusFS has four main modules, as shown in Figure 1. These are:

1. abacus file system implementation,
2. decision making module,

3. abacuscalc helper script for running the calculations,
4. database where extended metadata is stored.

C. *Abacus file system*

The FUSE-based file system is the core module of our solution. It uses a directory on another file system for backing storage. It is the only module that communicates with all other modules. The users and applications see it as a normal file system; however, the semantics are changed for files that are results of calculations done with the platform, i.e. files that have certain extended attributes set. When such a file is opened for reading, it is by default re-generated if needed, as explained above. After the file is accessed and read it can be 1) stored permanently or 2) not stored – instead re-generated on every access.

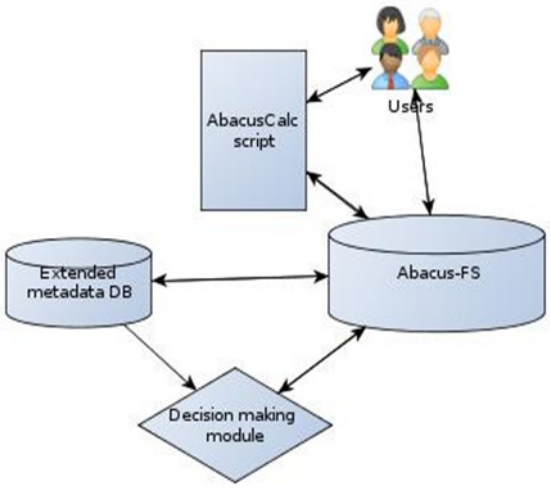

Figure 1. Over*view of the architecture*

D. *Decision making module*

The decision of 1) storing the file permanently or 2) re-calculate it every time it is accessed, is made by the decision making module. Since one of our requirements is to use the storage more efficiently and economically, we need to add some intelligence to these decisions. We propose an intelligent agent based on fuzzy logic [13], a proven principle that is widely used in fields such as computer science (e.g. bioinformatics, image processing, embedded systems), automation, process control,h etc.

The decision making process takes place every time the file is accessed. The agent must currently decide between the two options mentioned above. Even though this may seem trivial, the agent is extensible so that in the distributed version it will also decide where to put files and calculating processes, which files to replicate etc. Efficiency of resource use, performance, and reliability thus depends on this module.

We currently observe the following variables as the basis for the decision: the number of read accesses to the file, the size of the file, the number of time the calculation was run and the value user assigns to the file (optional).

E. *Helper abacuscalc script for running calculations*

The third module is the script for running the calculations. Whenever a user wants to run some calculation for the first time he needs to use this predefined script, which takes care of notifying the file system how the calculation is to be run, what input files it depends on, what output files it produces etc. For a trivial example, let us suppose that the user wants to run:
cat -n infile1 infile2 > outfile,
and he wishes the *outfile* to be managed by the file system as a calculation result.
Outfile must, of course, be located on the abacus file system, while the input files can be anywhere. The user must run the *abacuscalc* script *with* the following modified command line:
./abacuscalc.py cat -n -in infile1 -in infile2 -stdout outfile
Every input files must be preceded by *-in*, every output file by *–out*. Everything else are cosnidered as options. For pipes user must input *–pipe*. If any of these keywords is an option it must be preceded by *–lit*. Similarly, < is replaced with *-stdin*, > with *stdout* and *2>* with *-stderr*.

The abacusclac helper scripts forwards the information about the calculation using special, write-only files in a reserved part of abacus file system, similar to the Linux' *proc* file system.

F. *The extended metadata database*

The extended metadata database is a Redis [14] based database which is used to store extended metadata of the files and calculations. It is essentially a noSQL key value store in which we store two important types of data:

- associations between each output file and the calculation that produced it,
- all the informations about each calculation that are required to re-run it plus some statistics used by the decision making module.

Whenever a file is accessed the metadata database is consulted to check whether the file depends on (i.e. is the result of) a calculation. If this is the case then the record describing this calculation is also read.

The database may grow large, particularly once the platform is extended to distributed systems. We plan to use similar approaches as the existing metadata servers of Luster[15], PVFS[16] and other parallel file systems.

With this metadata database we have extended the metadata concept which would be harder to do if we were to use only extended attributes fields of the files. The problems with using extended attributes on the local machine would be the increase in file size an thus a performance problem. Using the metadata database is also simpler to develop, has no limitations for data model or size. But the major would be with the files that are not stored permanently for which we can not use extended attributes. Also in the future when AbacusFS is extended

on multiple machines the need for a centralized metadata database will appear.

III. IMPLEMENTATION

In this section we will describe some technical details of the modules introduced in the previous section and also interactions between them.

A. Communication between abacuscalc script and Abacus file system

As said before, the helper script uses write-only files in a special directory to forward the information on the calculation to the file system. Such a directory is created for each new calculation and named after a calcualtion's unique identifier (CUID) that the file system assigns to it. To illustrate how the communication works, we will show the equivalent commands that the user could enter for the before mentioned example of calculation: *cat -n infile1 infile2 > outfile.*
The whole process is explained in Table I. We will assume that abacus file system is mounted at */abacusfs*.

TABLE I. EXPLANATION OF THE COMMAND-LINE OF THE ABACUSCALC SCRIPT

Command-line equivalent of helper script action	**Comment**
# cd /abacusfs/newcalc	
# ls	Each *ls* in directory */abacusfs/newcalc* signals a new calculation. The file system will now generate a new CUID, e.g. 34ac5, and return the directory 34ac5 as the only file in /abacusfs/newcalc.
# cd 34ac5	
# echo 'cat -n \ /home/isak/infile1 \ /home/isak/infile2 \ > outfile' >cmd	Note that if the helper script is bypassed, which we only do here as illustration, absolute file paths must be used everywhere.
# echo '/abacusfs/isak/infile1' > in	
# echo '/abacusfs/isak/infile2' >> in	
# echo 'outfile' > out	
# cat status	Reading the status file signals that all the information has been written.

Once the *status* file is being opened for reading, the file system stores all calculation metadata to the database using the key *34ac5*. It then asks the decision-making agent whether this calculation should be first run right away. If the decision is no, the file system immediately returns as the contents of the *status* file a value that signalizes that the calculation has not been started. If, on the other hand, the decision is yes, the file system will:

1. run the calculation and wait for it to finish,
2. set an extended attribute of file *outfile* that will mark it as the result of calculation *34ac5*,
3. return an *OK* value as the contents of the *status* file. This will results in the user having to wait for the calculation to finish, which is the expected behavior.

B. Extended metadata database

Redis, which our metadata database is based on, is an advanced open source key-value store. The key of each record must be string while the value can be a string, a map (termed a hash in Redis), a list, a set, or a sorted set. Redis supports atomic operations such as appending to a string, incrementing the value in a hash etc. Redis works in-memory to achieve better performance but can also make data persistent by dumping the dataset to the disk on request or by appending each command to a log. In our solution we decided to dump the dataset to disk but also to use logging as well in the case of system. Since we use redis hashes as data structures to store information, it is important to underline that redis hashes are stored in such a way that takes very little space, so it is possible to store millions of objects in a small Redis instance.

Two pieces of data we currently store in the metadata server database are shown in Table II.

TABLE II. SAMPLE OF THE DATA STORED IN THE METADATA SERVER DB (FILE IS 'OUTFILE1:34AC5')

'34ac5' calculation hash	**Explanation**
'in': '/abacusfs/isak/infile1:1234 /abacusfs/isak/infile2:1234'	Input files with absolute paths and ctimes[1] of the files.
'inno': '2'	Number of input files.
'out': 'outfile:1234'	Output files with relative paths to /abacusf and ctimes of output files.
'outno': '1'	Number of output files.
'count': '45'	Number of times the calculation was run (the file has been re-calculated)
'time': '0.351'	Time it needed for the calculation to execute (last execution time).
'cmd': 'cat -n \ /home/isak/infile1 \ /home/isak/infile2 \ > outfile'	Full command-line of the calculation.
'nfa': '1034'	Number of times tihe file was accessed.
'uv': '3'	A value that user attaches to the file when running the calculation for the first time trough *abacuscalc* script.

C. Decision making module based on fuzzy logic

As said before, the intelligent decision making agent currently decides only between two options:

1. the calculation is run the first time with the *abacuscalc* script and afterwards every time the file is accessed but it is out-of-date, and

[1] Currently, when working on the local machine we read the ctimes from the stat structures of the files but when the soulution is extended on multiple machines we will need a metadata server which will serve all nodes. Of course that would meen that we also need a synchronization of the clock between nodes.

2. the file is not stored permanently but rather calculated every time it is accessed. Obviously, in this case the calculation should not be run when the helper script is invoked.

The agent bases its decisions on the following variables:

- number of accesses to the file (NFA) – this parameter tells us how often the file was accessed, which is, because the often the file is used will tip towards storing it permanently,
- size of the file (SF) – since one of the important issues is using the storage efficiently this parameter is very important,
- number of time the calculation was run (NCR) – this parameter will tell us how often is the file re-calculated,
- the value user attaches to the file (optional) (UV) – we need the parameter which will give the value that user can attach to the file, thus making it more or less important.

All variables except SF are stored in the metadata database. UV can be changed by the user and is by default 5 out of 10. The extreme values 0 and 10 are intended to override most of the influence of the other variables.

Each variable is a member of three fuzzy sets (small, medium and large). The boundaries of the sets are different for different variables, e.g. a smallish 30 MB file could have a 0.6, 0.4, 0.0 memberships in the three sets, respectively.

The decision variable DV is obtained to determine what to do with the file. It can take two possible intervals:

[1] [0 –50] – re-calculate every time
[2] [50– 100] – store permanently

The agent uses a set of rules to obtain such as:

if NFA == large and SF == small and NCR == small and UV == large then DV = store_permanently

if NFA == small and SF == large and NCR == large and UV = small then DV = recalculate_every_time

If the file is small in size, accessed frequently and has a high user value assigned it is optimal to store the file permanently. On the other hand if the file is large in size but accessed rarely and has small user value it may prove better to re-calculate every time the file is needed. Thus, user-given file importance, calculation time, frequency of access will tip the scales towards storing the file permanently and the output file size will tip it towards re-calculating the file when needed. One other important variable which will be added latter in the process is the time needed for the execution of the calculation. The shorter the calculation time the more likely it is that the file will be re-calculated and if the time grows large it may prove optimal to store the file permanently.

Since we have four input variables which are members of three sets we get $3^4 = 81$ rules. This currently crude process is a starting point for a search of optimal set of rules. Particularly the distributed version of the platform will require additional variables and a detailed study of the rules that achieve the best performance.

IV. TESTS

The AbacusFS platform obviously performs similarly to the underlying file system, only imposing an overhead when dealing with calculation-dependent files. The following operations could potentially induce a measurable overhead:

1. running the calculation for the first time, as opposed to running it without AbacusFS,
2. checking whether the file is up-to-date on each read access,
3. re-running the calculation when it is not up-to-date.

Note that the overheads of running calculations include the decision-making process. The performance of the in-memory files which are not stored permanently has not yet been tested.

The tests were conducted on the machine with Intel i7-2600 3.40 GHz CPU, Intel 80 GB SDD, on the 3.0.0. Linux kernel.

A. *Running the calculation for the first time as opposed to running it without AbacusFS*

We have conducted tests with the simple *cat a b > c* command where the input files *a* and *b* are located on the underlying file system and the output file *c* is stored on Abacus file system. The size of input files varied from 0 to 2 MB and tests were conducted with flushing the cache every time before the command was run and without flushing the cache. The results are in Tables III and IV and they show the increase of overhead with the increase of file size.

When comparing these results it can be seen that overhead also increases when the cache is flushed. Abacus file system uses a directory on the underlying file system for backing storage. FUSE in its implementation does not handle caches by itself, but relies on kernel caching. This means that the data is being cached twice since kernel sees abacus file system and the backend file system as different ones. We also did more tests to find out which part of the whole process takes most time. These tests showed that the time for execution of the command increases as file size increases and communication between abacuscalc script and abacus file system remains constant. This indicates latency issues more than bandwidth issues. We proved this by testing with flushing only page cache and directory entries and attributes, which showed that additional overhead comes when the page cache is flushed. Result is anticipated since FUSE always introduces some additional overhead related to data read/write operations. In the future we will try to optimize it and thus decrease the overhead.

TABLE III. TEST OF RUNNING THE CALCULATION FOR THE FIRST TIME ON ABACUSFS AND ON UNDERLYING FS WITH FLUSHED CACHE

Size of input files	AbacusFS – with flushed cache	Underlying FS – with flushed cache	Overhead
0 B	0.0544 s	0.0098 s	44.6 ms
4096 B	0.0639 s	0.0104 s	53.5 ms
0.5 MB	0.0729 s	0.0202 s	52.7 ms
1 MB	0.0825 s	0.0240 s	58.5 ms
2 MB	0.1117 s	0.0373 s	74.4 ms

TABLE IV. TEST OF RUNNING THE CALCULATION FOR THE FIRST TIME ON ABACUSFS AND ON UNDERLYING FS WITHOUT FLUSHED CACHE

Size of input files	AbacusFS – without flushed cache	Underlying FS – without flushed cache	Overhead
0 B	0.0177 s	0.0021 s	15.6 ms
4096 B	0.0180 s	0.0023 s	15.7 ms
0.5 MB	0.0288 s	0.0023 s	26.5 ms
1 MB	0.0360 s	0.0064 s	29.6 ms
2 MB	0.0496 s	0.0113 s	38.3 ms

B. *Checking whether the file is up-to-date on each access and re-calculating if it is not*

Option of checking whether the file is up-to-date and re-calculating files which are out-of-date is a major option of AbacusFS. Since file systems by default do not have this option the tests were conducted in two parts. First the files are up-to-date and we are measuring the overhead of read access to the files on abacus file system in opposed to the underlying file system. In second part the files are not up-to-date and they are automatically re-calculated. This measurement gives information on how much more overhead does the re-calculation part produces in the system. The tests were done only on small (6 bytes in size) files with and without flushing cache.

TABLE V. READ ACCESS TIME ON UNDERLYING FILE SYSTEM AND ON ABACUS FILE SYSTEM

Underlying FS – flushed cache	AbacusFS – flushed cache	Underlying FS – without flushed cache	AbacusFS – without flushed cache
0.0074 s	0.0151 s	0.0017 s	0.0035 s

TABLE VI. TIME NEEDED FOR READ ACCESS AND RE-CALCULATION WHEN THE FILE IS NOT UP-TO-DATE ON ABACUS FILE SYSTEM

AbacusFS – flushed cache	AbacusFS – without flushed cache
0.0232 s	0.0035 s

When comparing the results from Tables IV and V it can be seen that the re-calculation brings no additional overhead without flushed cache and with flushed cache only another 8 ms. This results is very important since the option of automatic re-calculation is one of the key advantages of AbacusFS.

C. *Workflows*

The third test which we conducted considers workflows. Since it was already said that workflow support is one of the key advantages of AbacusFS we needed to test it.

In order to test it we made a simple workflow which consists of simple cat commands:
cat a b > c,
cat a b c > d,
cat a b c d > e,
cat a b c d e > f,
where *a* and *b* are on the underlying file system and all other files or on abacus file system. The files are small in size (10 bytes). In underlying file system if the file *a* is changed it is necessary to manually run all the commands in order to get the file *f*. In AbacusFS if the file *a* is changed and file *f* read the whole workflow is automatically run and the file *f* re-calculated.

D. *Tests overview*

The conducted tests showed that for files smaller than 0.5 MB overhead is between 13 and 30 ms. The problem with larger files is within the FUSE implementation. Tests with the workflows show two things: 1) that the workflows are supported natively in AbacusFS and 2) that this does not causes any extra overhead.

The large files problem needs to be assessed more in the future and with optimizing the file system module decreased.

V. CONCLUSION

This paper has introduced the AbacusFS computational platform which tries to change the paradigm of storage such that the file system interacts with computations, thus connecting computational tasks and storage. It tries to solve two problems: 1) automating the process of running scientific calculations which are complex with lots of intermediate results and lots of dependencies thus reducing the need for user interaction; and 2) optimizing the use of storage to use the resources more efficiently and economically. Access to the files is changed in a way that if the file is a product of some calculation it can be re-calculated if some inputs of the calculation changed. Also some files are always re-calculated rather then saved permanently to save storage resources. All this is done by building a new file system and connecting the calculations and the file system with the extended metadata database that extends the metadata concept.

Preliminary tests showed the increase of overhead with the increase in file size. The tests have also shown that adding the option of automatic re-calculation (which also adds the option of workflow support natively) does not bring any new overhead to the system. The scalability to large number of files and calculations is currently being assessed.

Future work involves primarily refining the decision making process, refining the metadata concept, optimizing the FUSE based file system module and extending the solution to multiple machines (cluster/grid/cloud). The latter will also require incorporating a task scheduler, a resource manager and a distributed file system for backing storage. Furthermore we may add some prediction of users' behavior in order to achieve more automation as well as more efficient use of storage resources.

Abstract - Virtual teams are being increasingly used to run projects in globalized business environments. Virtual teams primarily rely on information and communication technologies to support many of communicative and collaborative activities that traditional collocated teams take for granted. To be efficient, virtual teams need more than just a plain set of tools dealing with different aspects of their operations. Comprehensive, integrated project management and project execution environment to support project activities is required. By integrating tools and methodologies such environment must enable efficient running of projects involving virtual teams. One of fundamental components of efficient virtual team environment is tool orchestration framework that enables seamless integration and value-added utilization of tools. This paper proposes such tool orchestration framework based on concepts of common information model, service oriented architecture and project processes. The proposed framework enables tools integration and orchestration in heterogeneous environments inherent to virtual teams. Utilization of the tool orchestration framework in conjunction with adequate project management techniques and methodologies improves virtual team project awareness whilst reducing the need for frequent interaction among team members, consequently resulting with increased virtual team performances. This paper describes basic concepts, architecture and utilization of the proposed tool orchestration framework for virtual team environments.

I. INTRODUCTION

In the current increasingly globalised economy, information and communication technologies provide support for establishment of virtual geographically dispersed teams. An indispensable task is efficient project management (PM) to coordinate the individual efforts and provide the conditions for creative collaborative work [1]. An integration of various tools and project management methods is proposed for that purpose. However, current tools have a number of drawbacks that prevent setting up of such integrated virtual team environments. The majority of these drawbacks come out of limited abilities for information exchange between tools from different vendors as well as inabilities to integrate the aspects from different tool categories [1], [4], [8].

At the beginning of each project virtual team members conciliate a set of tools and technologies that will be used during the project life cycle. In practice, most often it is preferred that all team members use the same tool for the same purpose. For example, MS Project is used to support PM activities, MS Outlook is used for e-mail exchange, Google Talk is used for instant messaging, etc. The advantage of this approach is the ability to get the most out of functionalities offered by each separate tool. Information exchange between team members using the same tools is more straightforward, and the information is presented in the same way to the sender and to the recipient. The drawback of this approach is the fact that team members are restricted in their choice of tools, which can negatively impact team's productivity. The practice has shown that teams whose members can freely choose tools and are able to experiment with technologies, achieve higher efficiency when compared to teams deprived of this choice [1]. This fact leads to another approach in which different team members are allowed to use different tools for the same purpose. For example, for the PM activities, some team members can use MS Project and some can use Oracle Primavera, for e-mail exchange and time scheduling some team members can use MS Outlook while others can use Google Gmail, etc. The advantage of this approach is that individual team members have freedom of choice to use tools with which they feel most comfortable. As previously indicated, this approach can have a positive influence on virtual team efficiency. However, practical implementation of this approach is somewhat difficult since current tools coming from different vendors are mostly monolithic, tightly coupled applications with fairly limited possibilities for mutual data exchange [4], [8].

Regardless of whether the teams use same or different tools for particular purposes, there is still very limited possibility of information exchange between tools from different categories, i.e. tools that are used to perform different functions during project life cycle. If information exchange and information correlation between various tools were possible, more efficient environment could be created compared to that when tools are used for just performing its specialized set of functions. For example, integrating aspects of collaboration tools into tools for PM and vice versa can positively contribute to the overall efficiency of virtual teams [2]. Furthermore, integration of other tools such as engineering tools (e.g. software development tools) used to produce project deliverables can also have additional positive influence on virtual team efficiency [3]. In order to support sequences of project activities, tool orchestration mechanisms are required. Such mechanisms provide not only tool interconnections

but also information that flows between team members participating in the process. The framework that supports tool orchestration enables integration of tools and project processes resulting in value-added tools utilization. Software tools that are not otherwise explicitly used for information exchange nevertheless provide additional useful information to the project team. Various tools provide certain parts of information that together contribute to creation of a comprehensive view of the current project state, referred to as project awareness. Utilization of a suitable tool orchestration framework increases the project awareness, compared to the one that can be achieved by simple information sharing using individual tools. Increased project awareness improves implicit coordination [4] and reduces the need for direct, synchronous interaction among team members, consequently resulting with increased virtual teams' performances [5].

Currently, there is a number of solutions that address the problem of virtual teams' tools integration. However, integration of tools from different categories and possibility of tighter integration between tools and project processes is quite limited. There is still room for improvement, so in this paper we propose a tool orchestration framework that can be utilized to support tight integration of tools, technologies and project processes into an efficient environment for running projects involving virtual teams. The proposed tool orchestration framework is based on standards and platform-neutral technologies and as such it is suitable to facilitate seamless integration and value-added utilization of current and future tools in heterogeneous environments inherent to virtual teams. In the following sections, basic requirements and fundamental concepts used for development of tool orchestration framework are elaborated. Implementation and utilization of tool orchestration framework is also described. Paper ends with the conclusion including brief description of future work.

II. BASIC CONCEPTS

Orchestration can be defined as activity sequences of a specific organization [8]. In computing, orchestration is defined as automated arrangement, coordination and management of systems and services aligned with business requirements [11]. In virtual team project environments, activity sequences compose project processes, while virtual team acts as an organization. In order to efficiently support and drive the execution of project processes, tools used in process activities must be orchestrated as well, with their usage aligned with project activity sequences. In virtual team environments, this can be accomplished with tool orchestration framework that meets the following requirements:

- Supports distribution of virtual team members, project functions and utilized tools
- Facilitates integration of different tools categories
- Facilitates integration of tools coming from various vendors
- Facilitates integration in fully heterogeneous IT environments
- Supports value-added usage of tools resulting in integration of project information and project processes
- Supports integration of tools with project management techniques and methodologies

In order to meet these requirements, conformity of incompatible tool information models must be achieved and a platform-neutral infrastructure for data exchange between tools must be implemented. The proposed tool orchestration framework achieves conformity of tool information models with the concept of common information model, while platform-neutral data exchange is implemented using service oriented architecture. A common information model in conjunction with service oriented architecture provides integration infrastructure that enables aligning process activities and supporting tools, resulting in orchestrated usage of tools tightly integrated with project processes. In the rest of this section, concepts of the common information model, service oriented architecture and project processes are elaborated.

A. Common Information Model

Currently, there are no significant standards that address integration of various tools, used by virtual teams. This includes PM tools, communication and collaboration tools and tools for design and development of project deliverables. Introduction of standardization would improve possibilities of tool integration and orchestration in heterogeneous environments, consequently improving the interaction between team members and increasing the project awareness. Introduction of standardization results in easier exchange of information and project deliverables throughout the project environment. They become more understandable to project team members. Tool orchestration framework proposed in this paper introduces standardization through the usage of the concept of common information model (CIM) [9] for the domain of project management and project execution. The proposed common information model is platform neutral, meaning its implementation is not restricted to a particular technology. The model as such is applicable in heterogeneous environments as a basis for development of individual tools, their application interfaces and data exchange protocols.

B. Service Oriented Architecture

The existence of the common information model is an important but not sufficient precondition for implementation of a tool orchestration framework. The common information model provides the basis for modelling of data and application interfaces, but it does not describe how the tools can be integrated to achieve data exchange. Requirements that the data exchange infrastructure must meet, are the technology independence enabling the usage in heterogeneous environments, flexibility to integrate various tools, and extensibility in order to support virtual teams of varying complexity and in different business areas. All of the above can be

satisfied by the concept of service oriented architecture (SOA). In a virtual team project environment, different service groups can be defined, such as services for project monitoring and control, services for communication and collaboration, services for performing work on producing project deliverables, etc. In the proposed framework, services are implemented by various software tools with application interfaces based on the common information model. Although the service oriented architecture can be implemented with different technologies, the most appropriate technology for usage in heterogeneous environments is the Web Services technology based on platform-neutral Extensible Markup Language (XML). Platform-neutral common information model and service oriented architecture constitute the integration infrastructure as foundation of tool orchestration framework.

C. Project Processes

The third concept on which the proposed tool orchestration framework is based is the concept of business processes [10] which in the context of the project environments can be referred to as project processes. This concept can be applied in the domain of project management and project execution. Application of this concept to projects involving virtual teams is of particular importance, since distributed project environments require more formalism in performing activities during project life cycle [1]. Proposed tool orchestration framework enables modelling of project processes suitable for virtual teams. As a part of planning, simulations can be performed, and based on simulation results, project plans can be optimized. Project monitoring and control activities are also positively influenced since project processes are more formally defined and their execution can be monitored through dedicated software tools. Process remodelling must also be supported, since project processes may change several times during project life cycle.

Tool orchestration framework built on aforementioned concepts enables improvements and upgrades of current and development of future tools. PM tools, communication and collaboration tools, as well as tools for producing project deliverables can be enhanced with features that enable greater automatism in planning, executing, monitoring and controlling of project activities during entire project life cycle. Usage of common information model based standardization together with service oriented architecture based integration makes implementation of the framework and development of tools that can be used in conjunction with it a much more straightforward task.

III. TOOL ORCHESTRATION FRAMEWORK IMPLEMENTATION

Based on concepts described in the previous section, tool orchestration framework for virtual team environments can be implemented. The framework comprises following components:

- Platform-neutral common information model
- Facilities to support tool integration and information exchange
- Facilities to support modelling, execution and monitoring of project processes
- Repository for storing project-related data
- User interfaces for a unified view of the project environment
- Application interfaces for exposing tools functions as services
- Adapters for data transformation from tool proprietary data models to common information model and vice versa
- Tools for project management
- Tools for communication and collaboration
- Product-oriented tools for development of project deliverables

All the components of tool orchestration framework are designed to be platform-neutral, so that they can be applied in heterogeneous environments. Heterogeneity of the environment is imposed by various software tools, since tools can be developed using various technologies and run on various platforms.

A. Standards Based Information Model

The fundamental component of a tool orchestration framework is the common information model that enables modelling of entities in the project management and project execution domain. The purpose of modelling is the creation of a formal domain model which can be utilized in development of systems, tools and technologies, used to support a project life cycle.

Common information model is based on PMBOK Guide [7] which provides generally recognized terminology and guidelines in the PM domain. It defines project management and related concepts and describes project life cycle and the related processes. According to PMBOK Guide, PM is accomplished through appropriate application and integration of PM processes. PM processes are grouped into five process groups according to the sequence: Initiating, Planning, Executing, Monitoring and Controlling, Closing, and into nine knowledge areas that bring together processes that have something in common. The process is defined as a set of interrelated activities performed to achieve a pre-specified product, result or service. Each process is characterized by its inputs (documents, plans, etc.), tools and techniques (mechanisms applied to inputs) and by resulting outputs (documents, products, etc.). PMBOK describes only PM processes, while product-oriented processes that specify and create project products are outside of its scope.

PMBOK Guide is widely accepted and it was adopted as a standard by American National Standards Institute (ANSI). This wide acceptance ensures understanding by large number of professionals that is necessary in the context of globally distributed virtual teams. Basing the common information model on such a widely accepted standard provides preconditions for further development and wider acceptance by vendors and end users.

The common information model unifies names, properties and relationships of entities in the project management and project execution domain. Common information model is a comprehensive abstract model that

contains classes used to describe entities applied during entire project life cycle. In other words, the common information model defines ontology as a foundation for information exchange and tools orchestration. Entities in the model represent process inputs, outputs and intermediates, providing unified data representations to tools utilized as support for performing process activities. For example, schedule chart templates are inputs into *Develop Schedule* process in which actual project charts are developed. Actual project charts are outputs of *Develop Schedule* process and in turn input to *Control Schedule* process. If schedule charts representations are unified, usage of the same scheduling tool in both processes is not mandatory.

For a platform-neutral definition of the common information model, Universal Modelling Language (UML) is used [6]. Model entities are described using UML classes. Entity properties are described with class attributes, and relations between entities are modelled by applying generalization, association, aggregation and composition of classes. The way of grouping according common characteristics, such as grouping by knowledge areas, is suitable for logical grouping of model entities. Entity grouping is modelled by UML packages, as illustrated in Figure 1. Entity modelling using UML class diagram is illustrated in Figure 2. with example of *Schedule* class from *Project Time Management* package. Class *Deliverable* represents outputs that comprise the product, as well as ancillary results, such as PM reports and documentation. This class can represent an abstract class inherited by classes from other packages, which in turn can define a specific deliverable to more detail.

Common information model defined in this way can be further extended to conform to some specific project environments or business areas. New entities can be added to existing packages or completely new packages can be introduced. Since PMBOK Guide describes only PM processes, extensions can be used to model entities belonging to product-oriented processes outside of PMBOK Guide's scope. Extensions do not influence compliance to original common information model since tools that cannot interpret specific entities can simply ignore them.

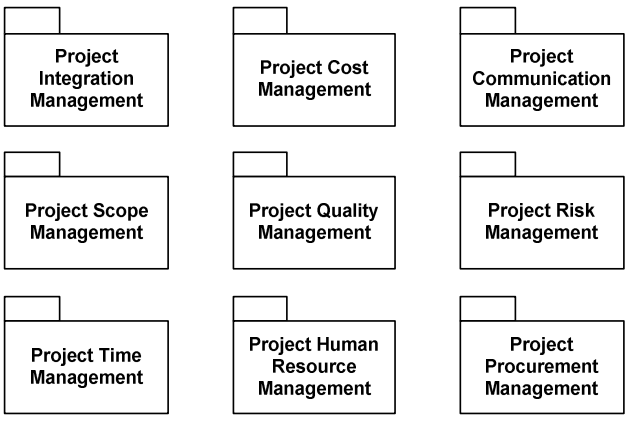

Figure 1. Common Information Model packages according to PMBOK knowledge areas

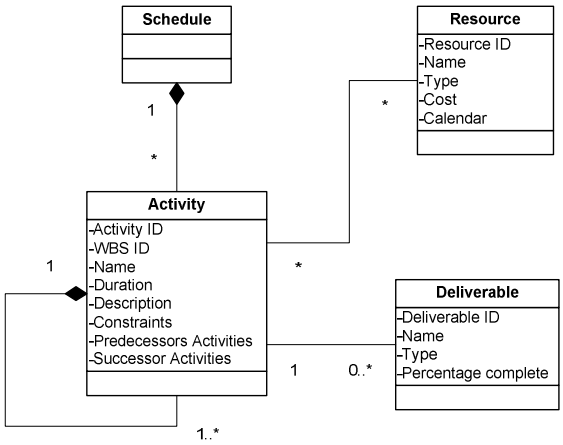

Figure 2. Example of entity modelling

Representation of common information model in UML defines data semantics. In order to facilitate the implementation of software tools, their application interfaces and adapters data formats in which information will be exchanged must also be defined. It is necessary to take into account the requirement for platform independence and the requirement for possibility to properly represent the common information model entities and their relationships. These requirements are met with Web Ontology Language (OWL) which is a family of knowledge representation languages for authoring ontologies. By using OWL, it is possible to model entity classes, their attributes and relationships. OWL serializations are based on XML and as such they satisfy the requirement for utilization in a platform-independent way. Mapping of common information model entities to XML enables encoding of message payloads suitable for exchange in heterogeneous environments.

Having in mind the wide acceptance of underlying components, the proposed common information model can be easily utilized in development of software systems and tools for the following purposes:

- Design and implementation of internal data structures and application interfaces for new tools development
- Design and implementation of adapters and application interfaces for customization of existing tools

It can be expected that the approach of upgrading existing tools with appropriate adapters and application interfaces would be more easily carried out in practice. It is more acceptable for tool vendors to amend existing tools with adapters and application interfaces to operate in common information model based framework then to develop completely new tools from scratch. Utilization of the common information model as a base for both modelling of internal data structures and application interfaces would be more plausible when new versions of existing or entirely new tools are developed. The prerequisite for both scenarios is a wider acceptance of the common information model. This can be accomplished by developing open source components to be reused for tool development and customization, including development of adapters for currently widespread and generally recognized software tools.

B. SOA based Tool Integration Infrastructure

Common information model sets the foundation for implementation of the standardized tool integration infrastructure that further supports tool orchestration. The proposed tool integration infrastructure is based on SOA paradigm and Web Services technology. By using such infrastructure, tool functionalities can be exposed to the project environment as services with well-defined inputs and outputs. Tool orchestration framework implemented utilizing SOA based integration infrastructure includes the following components as illustrated in Figure 3:

- Web Services interfaces for exposing tool functionalities and binding to the framework
- Metadata Repository containing information about service access, data semantics and data syntax
  - WSDL - XML based Web Services interface descriptions
  - OWL - XML based description of data semantics and data syntax
  - Common Information Model - foundation for definition of data semantics and data syntax
- Service Repository as a central point for services discovery
- Service Orchestrator to drive tool orchestration integrating tools and project processes

Integrated software tools retain their basic functionalities. On top of that, tools can be enhanced with new functionalities that come out of novel possibilities of data exchange and tools integration. Existing software tools have been primarily designed for performing a set of functions designated for usage by particular project roles (e.g. project manager). Tools integration framework enables improvements in a way that team members performing different project roles can have improved insight into the project. This can be done partly through individual enhanced tools or through a comprehensive user interface such as project portal that integrates and correlates information from various sources and provides a unified view of the project environment.

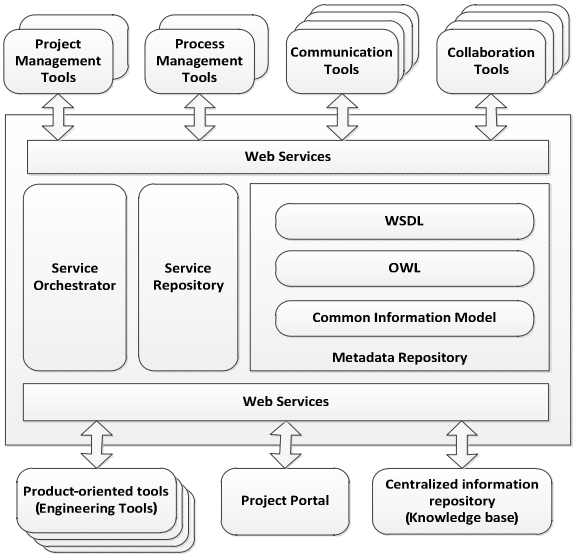

Figure 3. SOA based Tool Orchestration Framework

Integration infrastructure can be configured in a way that information arising from the project environment during project life cycle is stored in the central information repository. This repository represents the source of integrated project information throughout the life cycle of the project. After project completion, stored information will remain as a knowledge base for exploitation in future projects.

The proposed orchestration framework can be used for implementation of project environments according to both bottom-up and top-down principles. Implementation of the project environment according to bottom-up principle implies the possibility of utilization of the existing tools that can be customized by using the proposed tool integration infrastructure. This primarily implies the development of proprietary data model transformation adapters and application interfaces for interconnection to the orchestration framework. This principle does not significantly affect existing tools functionalities and architectures and does not require their major modifications. Implementation of the project environment according to top-down principle implies that software tools are made in a way that their internal data structures and functions are in line with the common information model. Ideally, the need for transformation of tools proprietary data models would completely disappear, and fully standardized project environment could be achieved. However, this approach requires significant modifications of existing tools or creation of entirely new tools. This significantly hinders the possibilities of practical implementation. It can be expected that in the real-world project environments, bottom-up principle would be applied more extensively. The main reason is the possibility of using existing, widely spread software tools with minimal requirements for modifications and upgrades. For tool vendors this is the most attractive solution since less time and money can be spent to achieve noticeable results. Over time, through releases of new versions of existing tools, or the emergence of new tools, usage of tools fully based on a standardized common information model can be expected.

C. Tool Orchestration Framework and Management of Project Processes

SOA based tool integration infrastructure enables information exchange in heterogeneous environments. That contributes to improved interaction among virtual team members, but by itself it is not sufficient to achieve targeted effects of tool orchestration. To complete implementation of the tool orchestration framework, it is necessary to improve the manner in which tools are used. While common information model is used to model activity inputs and outputs, and integration infrastructure is used for their exchange, actual project work is performed through tool-supported activities. To be able to efficiently drive project processes, tool usage must be orchestrated and aligned with project process activity sequences. Orchestration of tools is implemented through orchestration of their associated services. By utilizing framework's Service Orchestrator component, services can be orchestrated to drive various processes including both PM processes and product-oriented processes.

Project can be defined as a set of project processes. Each process can be composed of a series of simple and complex activities. Simple activities can be associated with a single service. A complex activity can be considered as a subprocess, which can be further broken down into a series of simple or complex activities. For example, *Develop Schedule* process can contain activity *Create Schedule Chart*. If creation of a single chart is required, this activity can be considered as a simple activity. But, if creation of more than one chart type (e.g. milestone chart and network diagram) is required, this activity can be considered as a complex activity, since it can be further decomposed and supported by more than one service, i.e. tool. Services that take part in activities, have precisely defined inputs and outputs described with entities of the common information model. Services can be implemented solely through tools (e.g. storing information in a central information repository) or by project team members using certain tools (e.g. creation of a schedule chart in a PM tool). For the purpose of project processes modelling, execution and monitoring standards like Business Process Modelling Notation (BPMN) and Business Process Execution Language (BPEL) can be used, along with tools for Business Process Management (BPM). Example of modelling PM and product-oriented processes using BPMN is illustrated in Figure 4.

While common information model describes a static view on the project, process modelling provides its dynamic view enabling new possibilities during project life cycle. Planning can include process simulations and optimizations, processes can be more clearly defined and more easily followed by all team members, while process execution can be more automated with more transparent monitoring and control. Although it is desirable to strive to achieve standardization of project processes, it is not always an easy task, especially in virtual team environments. One reason is that the flow of the project is dynamic by its nature and as such can be subject to rather frequent changes. This is especially true for development projects such as projects of software development. Another reason lies in the maturity of the organization and virtual team performing a project. With higher level of maturity, project processes will be more standardized and less subject to changes.

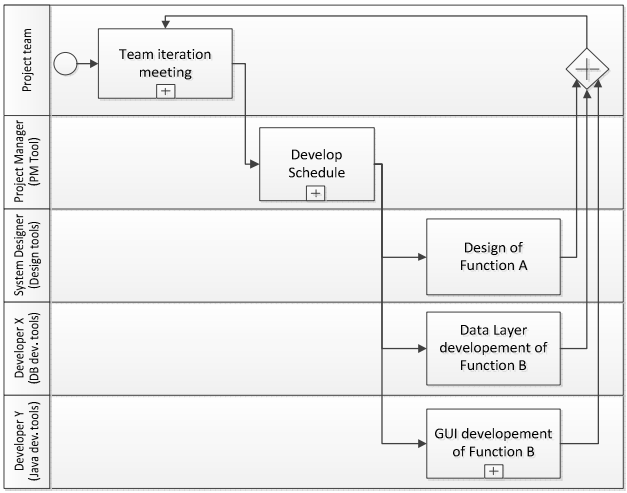

Figure 4. Example of software development iteration processes modelled using BPMN

Besides modifications that take place during the project (mostly due to some unforeseen circumstances), project processes can also be purposely modified as part of project closing. Processes can be optimized based on experience gained while project work was carried out.

IV. CONCLUSION

This paper proposed standards based tool orchestration framework, suitable for usage in heterogeneous environments inherent to virtual teams. The proposed framework is based on concepts of common information model and service oriented architecture and as such provides a base for development of standards based software tools. The framework gives virtual teams the possibility to use most suitable tools in an orchestrated way to be aligned with and to drive the project process activity sequences. Utilization of the proposed framework enables tighter integration of project information and project processes, consequently resulting in increased virtual team performances. Currently, methodological framework suitable to manage projects involving virtual teams is also being developed. Methodological framework together with tool orchestration framework, proposed in this paper, will constitute an integrated framework for management of virtual teams. A prototype of the integrated framework will be implemented and its efficiency will be practically verified.

Abstract - Series of benchmarking of 210K atoms of inverse micelle/oil/water system have been carried out on Bulgarian BlueGene/P at Bulgarian Supercomputing Centre and on computational resources of Armenian National Grid Initiative (ArmGrid). The experiments show that the linear increase of speed of calculation with the increase of number of processors has been obtained. It should be noted that no saturation is observed and finally we received 0.121day/ns using 4096 processors of BlueGene/P, meanwhile the data within the ArmGrid infrastructures shows the breakdown in scaling, which is depends on communication time between processors.

I. INTRODUCTION

High Performance Computing (HPC) allows scientists and engineers to solve complex science, engineering and business problems using applications that require high bandwidth, low latency networking, and very high compute capabilities. HPC has come a long way for life sciences. Molecular dynamics (MD) methods [1] are an established mechanism for determining the equilibrium and transport properties of a classical many-body system. Today, molecular dynamics techniques are being used to simulate larger and more complex biological systems.

The formation of microemulsions can be observed by the self-assembly of complex system consisting oil, water and surfactants. The mentioned complex systems have been intensively investigated both theoretically and experimentally motivated by their potential use in enhanced oil recovery. With the rapidly increase of hardware power, the MD study of mentioned complex systems became a unique tool for deepen understanding the physics of phenomena occurring at microsecond timescale. Namely, the MD method is rather good for the study of such kind systems and to the best our knowledge there is no published paper on mentioned systems. In this regards, the usage of HPC supercomputer resources became an important for the detailed investigations of mentioned complex systems.

Since 2004, the first HPC facility, the Armcluster system [2] was deployed in the South Caucasus region, which was achieved 523.4GFlops performance. Several MD studied have been done on Armcluster platform involving the simulation of small size system. Now ArmGrid [3] infrastructure consists of seven Grid sites located in the leading research and educational organizations of Armenia. Apart from computing (500 cores) and storage resources, core Grid services that enable seamless access to all resources are provided to national users. The usage of ArmGrid resources make it possible to model and simulate more complicated systems including the microemulsion droplets, which are of special interest.

ArmGrid infrastructure successfully interconnected with the international [4] and regional [5] Grid infrastructures. For this investigation, mainly the below mentioned two most powerful computer architectures presently available in the South East European region and in Armenia have been used: Bulgarian IBM Blue Gene/P [6] contains 8192 densely packed microprocessors and runs at 23.42 trillion operations per second and Armcluster.

Recently, a number of benchmarking simulations were carried out both on grid infrastructures [7] and supercomputers [8], using the most popular software packages GROMACS [9] and NAMD [10].

NAMD is a parallel molecular dynamics code designed for high-performance simulation of large biomolecular systems. NAMD scales to hundreds of processors on high-end parallel platforms, as well as tens of processors on low-cost commodity clusters, and also runs on individual desktop and laptop computers. NAMD works with AMBER and CHARMM potential functions, parameters, and file formats. The NAMD package was benchmarked on Blue Gene/L system using ~8000 processors [11] achieved 1.2 TF of peak performance for cutoff simulation and ~0.99TF with PME method.

The purpose of this research is to estimate the parallel performance of NAMD package BlueGene/P (IBM Blue Gene/P: PowerPC 450 processors, a total of 8192 cores) at Bulgarian Supercomputing Centre and compare to our previous data, which is done on the ArmGrid infrastructure [12]. In overall, about 100ns of simulation run was carried out on anionic sodium dodecylsulfate inverse micellar system with presence of polyampholytes at various pH (see Figure 1).

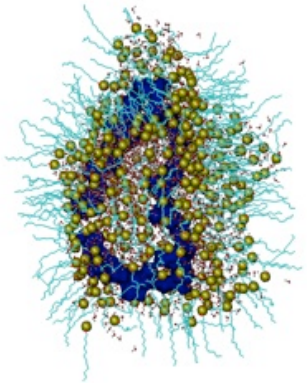

Figure 1. Anionic sodium dodecylsulfate inverse micellar system with presence of polyampholytes at pH=9.

II. BENCHMARKS AND RESULTS

The NAMD package using CHARM++ communication library is a C++ based parallel program, the parallelization of which is done via hybrid force/spatial decomposition. The system of about 210K atoms is used as a benchmarking system (inverse micelle in oil). As a timestep 1fs is used and the PME electrostatics and van der Waals forces truncated at 1.2nm.

The Molecular Dynamics study of mentioned system makes it possible to deepen understand the mechanism of interaction of anionic sodium dodecylsulfate and cationic/anionic/noncharged polymer and to receive features of systems receiving an significant impact in the oil industry.

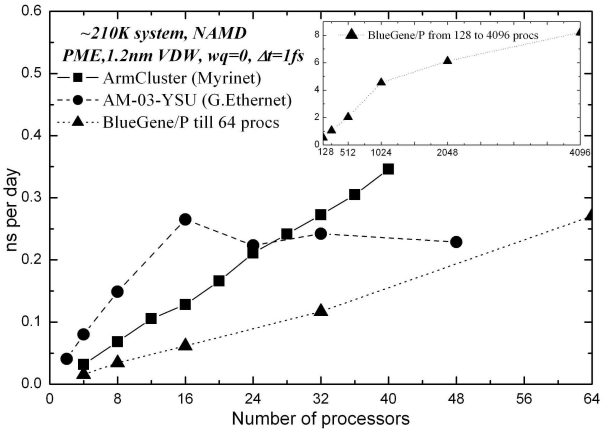

Figure 2. The NAMD performance and the estimation of ns per day against the number of processors for BlueGene/P, ArmCluster and AM-03-YSU sites.

The benchmarking data was shown in Figure 2. As a comparison, we have provided also our previous data, which have been done using the computational resources of the ArmGrid infrastructure. The benchmark ploting shows that we obtain almost linear increase of calculation speed with the increase of number of processors in case of BlueGene/P. One can see that there no saturation points and for 4096 processors we get about ~0.12 days/ns results. In case of Grid infrastructure, we see the breakdown in scaling, dealing with interconnection between processors, i.e. it is naturally to suppose, that the software spends more time on interconnection between processors. For this purpose, series of micro benchmarking on MPI implementations [12] for Myrinet and Gigabit networks have been done.

The data implies that the scaling on clusters with high performance of Myrinet and Infiniband networks is rather better than the clusters using Gigabit Ethernet network that is to say, we see the breakpoint in scaling followed by disappearing of such kind of "critical points" when the system size exceed the so called "critical amount" of atoms [12].

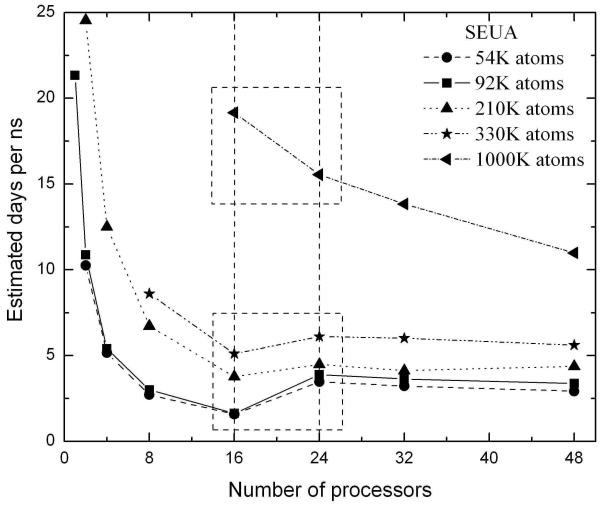

Figure 3. The NAMD performance and the estimation of days/ accordingly for 1000K, 330K, 210K 92K and 54K atoms.

In Figure 3 the benchmarking data of 54K, 92K, 210K, 330K and 1000K systems using computational resources (48 cores, Gigabit Ethernet) of the Grid site located in the State Engineering University of Armenia are shown. It is clearly seen that when the system reaches up to 330K atoms, the breakdown in scaling disappears and we track almost continuously decrease of calculated parameter. It is important to mention that optimal number of processors is 16 (see Figure 3).

III. CONCLUSION

Thus, the benchmarking results provided below, implies that for complex systems consisting more than 200K atoms the usage of supercomputers is rather efficient than the computational facilities of the ArmGrid infrastructure. For relatively small systems up to 200-300K atoms, with the increase of processors we track that the computation spend more time on communications between processors, as in case of Grid sites of the ArmGrid infrastructure, whereas the benchmarking on BlueGene/P shows almost gradually increase of speed of calculation with the increase of processors. Note that for relatively small amount of processors (up to 64 processors) the speed of calculation is surely better on

ArmGrid sites due to the type of processors (BlueGene/P with PowerPC 450 - 850MHz vs worker nodes with Intel 2.0GHz to 3.06GHz frequency). Finally, the presented results should be very important to choose the appropriate amount of processors in case of computational resources; meanwhile, the supercomputers show almost ideally behavior with the increase of processors.

It is further expected to start the benchmarking on GROMACS software package to testify the sensitivity on system sizes using BlueGene/P resources at Bulgarian Supercomputing Centre, as well as on Grid sites using graphics processing units (GPU), because high degree of parallelism and floating point arithmetic capability of GPUs can attain performance levels twenty times that of a single CPU core.

DISTRIBUTED PROGRAMMING AND CLOUD SERVICE

Accessing and Steering the Elastic OLAP Cloud

Abstract – A typical cloud platform provides capability of scalability, elasticity and fault tolerance. Moreover, it is designed to deal with high volumes of data on nearly unlimited number of machines. On-Line Analytical Processing (OLAP), a kernel part of modern decision support systems, allows interactive analysis of multidimensional data of varied granularity. A combination of the Cloud Computing and OLAP technologies brings challenges in providing OLAP analysis services in distributed environments. This paper first presents an overview of our on-going research of Elastic OLAP Cloud Platform. Then it introduces our design and implementation of a multi-tier client system, which on one hand interacts with the Elastic OLAP Cloud platform, provides Web based Graphical User Interfaces for administration of virtual OLAP cubes and performing OLAP analysis queries, and on the other hand, interacts with the OGSA-DAI middleware to access heterogeneous data sources and load integrated data into the Elastic OLAP Cloud platform. The communication between the client and the platform is based on our home-grown OLAP Modeling Markup Language (OMML), which is also presented in this paper.

I. INTRODUCTION

Cloud Computing is the evolution result of virtualization technology, network storage technology, distributed computing, parallel computing and Grid Computing. It shares several characteristics with these computing models and brings a more flexible and more scalable computing model. Cloud Computing provides, through Internet, supercomputing power, which is made up from a large number of relatively low cost physical computing instances. Utilizing service models like Software as a Service (SaaS), Platform as a Service (PaaS) and Infrastructure as a Service (IaaS) the Cloud Computing distributes its computing power to the end user, which normally could be only a "thin" client, e.g. a Web browser without any programming requirements.

On-Line Analytical Processing (OLAP) is an important analytical approach of data warehouse technology. It has been widely applied in business, industry and scientific research. OLAP supports complicated analysis on shared multi-dimensional data. It provides support to decision making with analytical query results which are intuitive and easy to understand. The expected data of an OLAP system could be distributed in different locations and may be from different data sources. The size of the data is normally huge in volume. The core of an OLAP implementation is the OLAP Cube consisting of numeric facts called measures, and categorized by their dimensions.

Cloud Computing provides scalable compute infrastructure based on dynamic configurable virtualized hardware resources. The most significant characteristics of Cloud Computing are virtualization and elasticity. The combination of Cloud Computing and OLAP has led to the prototype of our *Elastic OLAP Cloud Platform* introduced in [1], which can efficiently utilize Cloud Computing infrastructure and provides scalable OLAP service through Representational State Transfer (REST) Web Service interfaces [2]. REST is a software architecture style, which indicates that interaction with the Elastic OLAP Cloud should be achieved by Hypertext Transfer Protocol (HTTP) request and response. But, manually initiating an HTTP request and handling the response is not an easy task, we need a user-friendly way for interaction with the RESTful[1] interfaces so to access and steer the Elastic OLAP Cloud Platform, this is also the motivation for the efforts presented in this paper.

Accessing and steering the Elastic OLAP Cloud Platform includes the following aspects, and should be available for two user groups with different privileges:

- OLAP Query Client: the user from this group can access the Elastic OLAP Cloud Platform, initialize OLAP Query and get OLAP analytical results.
- OLAP Administrator: Besides performing OLAP analysis, the user from this group has also a privilege for management of OLAP cubes, accessing heterogeneous data sources, transferring the raw data to the Elastic OLAP Cloud Platform, and loading the data into specified OLAP cubes.

Google Web Toolkit (GWT) is an open source framework based on Java and it is used to fast develop Asynchronous JavaScript and XML (AJAX) Web applications. GWT provides a lot of attractive Web-based Graphical User Interface (GUI) components. Further, the GWT developer can efficiently design and implement multi-tier front end web application and easily interact with various kinds of backend business logic. Such a front end Web application can be a good candidate for Cloud Computing. To access and steer the Elastic OLAP Cloud Platform, we have applied GWT and developed a multi-tier client system with two web based GUIs for users from different privilege groups.

Before loading data into the OLAP cubes on the Elastic OLAP Cloud Platform, the raw data from different kinds of data sources should be integrated and converted into a unified format, this can be achieved by an Open Grid Services Architecture - Data Access and Integration

[1] A software architecture conforming to the REST style constrains is referred to as being "RESTful".

(OGSA-DAI) server. OGSA-DAI is a middleware service, which aims to provide an efficient way for data access and integration in distributed computing environments. It allows the user or other services to access various kinds of heterogeneous databases including relational databases, XML databases, and also file system-based data repositories. It enables sharing data resources at a high level, so, co-processing and accessing to the data sources becomes more efficient, transparent and reliable.

As our client system has a multi-tier architecture, each tier of the architecture should understand each other by agreement on some common standard. Our home-grown OLAP Modeling Markup Language (OMML) is applied to represent all OLAP related information including OLAP cube description, OLAP queries, analytical results, and so on. Data in the system are represented in the WebRowSet XML format, which is an efficient way for transferring large amount of data in distributed environments through Web Service interfaces.

This paper describes our original design and implementation of the Web-based multi-tier client system, which aims at providing a user-friendly way for accessing and steering the Elastic OLAP Cloud Platform.

The rest of the paper is organized as follows. Section II gives a short overview of the Elastic OLAP Cloud Platform and related previous work. Section III presents the architecture of the client system including description of each tier. In Section IV, the eXtensible Markup Language (XML) applied in the system is discussed. Section V describes the data flow and the way of data integration in the system. In Section VI, we present several GUI screenshots of the implemented client system. Section VII makes conclusion and gives ideas for further research and development.

II. BACKGROUND AND PREVIOUS WORK

The OLAP engine [3] originated from the GridMiner project[2] is the most essential part of the Elastic OLAP Cloud Platform. This engine is a Multi-dimensional OLAP (MOLAP) implementation [4], which in comparing with the Relational OLAP (ROLAP) has at least two advantages [5].

1) Only distinct dimension members are stored for indexing and locating measures, which implies better storage resource utilization.

2) Fast measure indexing algorithm, which implies better processing performance.

The OLAP engine was developed in the era of Grid Computing, besides fulfillment of all requirements of an efficient OLAP implementation [6], it was designed to be deployed to the distributed computational resources. The engine uses Master/Hosts approach as its distribution structure [7]. The master compute node can not only distribute the storage load, but also distributes the work load, i.e. huge amount of data can be distributed to host compute nodes, besides, all the host compute nodes can perform OLAP analysis simultaneously, and the final analysis result is than aggregated at the master compute node.

The Elastic OLAP Cloud Platform [1] is our further research and development effort on base of the OLAP engine developed within the GridMiner project. The platform provides a set of RESTful Web services managing the multidimensional data model in a Cloud environment. The services store, manage, analyze data and answer OLAP queries in a fully distributed manner. The size of the platform is dynamically scalable in the runtime upon OLAP administrator's requirements. The scalability of the platform is implemented via an infrastructure broker mechanism, which means that there is an infrastructure resource broker in the platform, which provisions compute resources from the Cloud infrastructure provider to the OLAP Cloud. In this way, each part of the platform (the Cloud infrastructure provider, the infrastructure broker and the OLAP Cloud) are substitutable and loosely coupled to each other (they cooperate with each other also through RESTful Web Services). A good practice for designing software architecture of a cloud computing platform suggests that the more loosely coupled the components of the system are, the better it scales [8].

The feasibility and effectiveness of the Elastic OLAP Cloud Platform was proved by experiments on the Amazon Elastic Computing Cloud (EC2) [9], which was used as a test cloud infrastructure provider. The performance analysis based on the experiment results has shown that the platform can take advantage of the Cloud Computing parallel computation model by low cost and high benefit of the parallel OLAP operations.

III. MULTI-TIER ARCHITECTURE OF THE CLIENT SYSTEM

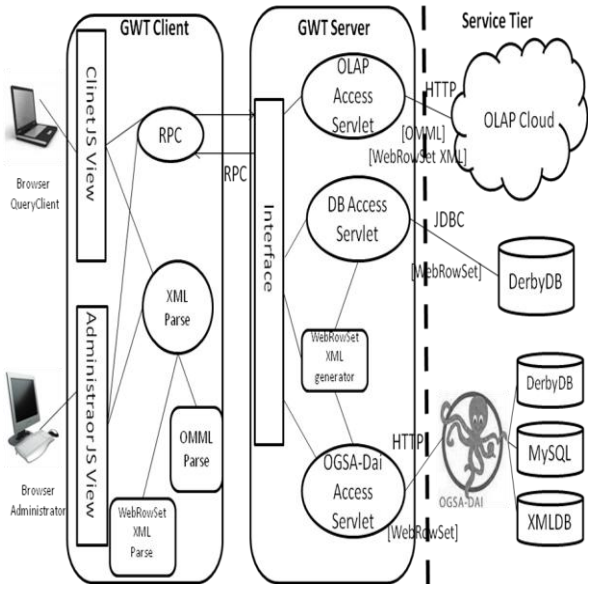

Figure 1. The multi-tier architecture

The architectural overview of the system is illustrated in Figure 1. The part on the left to the dashed line is a

[2] http://www.gridminer.org

typical architecture of the GWT framework [10]. There are two tiers in this part. The first one is the GWT client tier that provides two Web-based GUIs with AJAX features for users from two different groups: OLAP Query client and OLAP Administrator. The second one is the GWT server tier, which is also a part of the GWT framework. The GWT server tier contains several Servlet logics and interacts with both the GWT client tier and the back end business logic of the service tier. The right part of the dashed line is the service tier including three services which play the role of back end business logic in the architecture. The communication between GWT client tier and GWT server tier is achieved by GWT Remote Process Call (RPC) [10], the communication between GWT server tier and service tier is achieved through different Servlets either by HTTP or by JDBC.

A. The GWT client tier

The GWT client tier is the presentation layer, which directly interacts with the user. The main tasks of the GWT client tier include:

- JavaScript views: Implementation of two different AJAX GUIs, one for OLAP Query Client and one for OLAP Administrator.
- RPC: Implementation of RPC communication between GWT client tier and GWT server tier.
- OMML Parser: Implementation of the function for converting the query table initiated by the user to the OMML document and converting the OMML query result from the Elastic OLAP Cloud Platform to the result table of the GUI.
- WebRowSet XML Parser: First, in the GWT server tier the raw data from the Derby database or from OGSA-DAI server will be converted into the unified WebRowSet XML format. Then the data will be passed to the GWT client tier; here the WebRowSet XML format data is parsed and presented in the form of a grid table to the OLAP Administrator, who can then decide, whether the data shown in the table should be loaded into the OLAP cubes.

B. The GWT server tier

The GWT server tier is an intermediate layer, which separates the GWT client tier and services tier. Servlets in this tier can be called from the GWT client tier through RPC interface. On the other hand, the Servlets work as clients of different back end services:

- OLAP Access Servlet: This Servlet communicates with the OLAP cloud through HTTP and are implemented by Apache Wink client toolkit. The Servlet handles the request to send to the OLAP cloud, transferring parameters and getting response back. For loading data to the OLAP cloud, the Servlet transfers data in the WebRowSet XML format to the OLAP cloud. For querying OLAP, the Servlet communicates with the OLAP cloud by exchanging OMML messages.
- Database Access Servlet: This Servlet implements data access directly to a relational database - Apache Derby database. It uses JDBC to connect to the database and get data from the database and transform the raw data into the WebRowSet XML format and sends it to the GWT client tier.
- OGSA-DAI Access Servlet: This Servlet implements data access to the OGSA-DAI server, which integrates data from heterogeneous data sources and provides it to the Servlet. The Servlet transforms the raw data into the WebRowSet XML format and sends it back to the GWT client tier.

Besides the three Servlets in this tier, we have also implemented a WebRowSet XML generator module, which is embedded both in the Database Access Servlet and OGSA-DAI Access Servlet. Its main function is converting the WebRowSet Java object, which holds the resulted data, to the WebRowSet XML document.

C. The service tier

The service tier contains all the back end business logics, which are provided through different kinds of interfaces. The client system can load data from databases either through the Apache Derby Database or through the OGSA-DAI server, but our data source is not limited to databases. In the service tier, it is easy to extend more data sources of other types as we have a loosely coupled architecture. Data from different sources are converted into a unified format and can be loaded into OLAP cubes in the Elastic OLAP Cloud Platform.

- Elastic OLAP service: The Elastic OLAP Cloud Platform provides OLAP services to the client systems through RESTful Web Service interfaces. Through these interfaces, the OLAP Query Client can access the Elastic OLAP Cloud platform and perform OLAP analysis, while OLAP Administrator can manage OLAP cubes and decide the data flow from data sources to specified OLAP cubes.
- Apache Derby Database: Apache Derby database is a typical relational database. A Derby database server is setup and configured in the service tier. It provides relational database access services through JDBC.
- OGSA-DAI Service: The OGSA-DAI provides data access and integration service through Axis2 Web Service[3] interfaces. The OGSA-DAI service is also a suitable candidate to be deployed in Cloud Computing environment to enhance its scalability.

IV. REPRESENTING OLAP MODELS AND ASSOCIATED DATA

A. OMML

The OLAP Model Markup Language (OMML) is designed aiming at providing a consistent OLAP models

[3] http://axis.apache.org/axis2

description standard, which should be independent of any target OLAP platform. This standard representation can be used by other OMML compatible applications for further processing of the same data cube, for example data mining tools or graphical representation of OLAP models. With OMML a sufficient level of interoperability between different OLAP systems can be guaranteed. So, two or more OLAP systems can use OMML to cooperate and exchange information and data.

OMML was firstly introduced and drafted in [11]. We have further developed and further developed it for Elastic OLAP Cloud Platform. OMML is applied as communication language between the Elastic OLAP Cloud Platform and the client system. Components of OMML can be categorized into following groups, which can also be seen as requirements to OMML:

- Representation of OLAP analytical operations, this part can be used for initializing customizable OLAP queries.
- Representation of the data cube itself including its metadata about dimensions, hierarchical relations between dimensions and dimension members.
- Representation of OLAP analytical results.

Figure 2 is an example for OMML representation of a simple data cube with 4 data fields. The cube has three dimensions, "Location", "Year", "Product", and a measure "Sale". There are no hierarchical relationships between the dimensions. Dimension members are located inside <value> elements.

```
<DataDictionary numberOfFields="4">
  <DataField name="Location" optype="categorical"
    dataType="string" measure="false" >
      <Value>Austria</Value>
      <Value>USA</Value>
  </DataField>
  <DataField name="Year" optype="categorical"
    dataType="integer" measure="false" >
      <Value>2011</Value>
      <Value>2010</Value>
  </DataField>
  <DataField name="Product" optype="categorical"
    dataType="string" measure="false" >
      <Value>PC</Value>
      <Value>TV</Value>
  </DataField>
  <DataField name="Sale" optype="continuous"
    dataType="double" measure="true"/>
</DataDictionary>
```

Figure 2. OMML representation of a data cube

An OLAP Query always comes with a specific OLAP operation and a data range specification for each dimension of the data cube. Figure 3 is an OLAP Query example, which leads to a "sum" operation on specified data. The semantic meaning of the example query is: *"How many PCs in total were sold in Austria in the past two years?"*

```
<Query id="1" method="sum">
  <Parameter name="Product">
    <Value>PC</Value>
  </Parameter>
  <Parameter name="Location">
    <Value>Austria</Value>
  </Parameter>
  <Parameter name="Year">
    <Value>[ANY]</Value>
  </Parameter>
</Query>
```

Figure 3. OMML representation of an OLAP Query

After execution of the above example OLAP Query, the related single-value result can be given in OMML as shown in Figure 4.

```
<Result id="1">
  <Value>543</Value>
</Result>
```

Figure 4. OMML representation of an OLAP Query

B. WebRowSet XML

Normally, WebRowSet XML documents are generated following the standard WebRowSet XML schema definition. A WebRowSet XML document contains three separated parts: properties, metadata and data. It is a well structured and space-saving data format to efficiently represent data from relational databases or other data sources. Besides, a WebRowSet XML document can be easily and efficiently processed by various implementations even when volume of data is huge [12]. All these features make the WebRowSet XML a suitable format for our system to transfer data through Web Services.

V. DATA INTETGRATION AND DATA FLOW

In the design of the client system there is an Apache derby Database server, which enables direct relational database access. But more generally, we can access different kinds of distributed database sources through an OGSA-DAI server, which provides integrated data in a unified format to the Elastic OLAP Cloud Platform. An OGSA-DAI server hides heterogeneities of its related databases and it shares most of the concepts and requirements of general distributed systems [13]; these include access transparency, location transparency, migration transparency, security transparency etc.

The data flow in the client system can be illustrated for OLAP Query Client and OLAP Administrator respectively due to different privilege and function requirements of the these two user groups.

A. Data flow of the OLAP Query Client

Figure 4 illustrates the data flow of the OLAP Query Client. Firstly, the OLAP Query Client should initiate

query in the Query Client's GUI and fill in the form with query parameters to specify the range of data and the required OLAP analysis. The form will be then parsed by the OMML parser module and converted to an OMML document. After that, a RPC connection will be established between the GWT client tier and GWT server tier, through the RPC connection the OMML document will be transferred to the GWT server tier and then will be sent to the OLAP cloud by the OLAP Access Servlet through the HTTP connection.

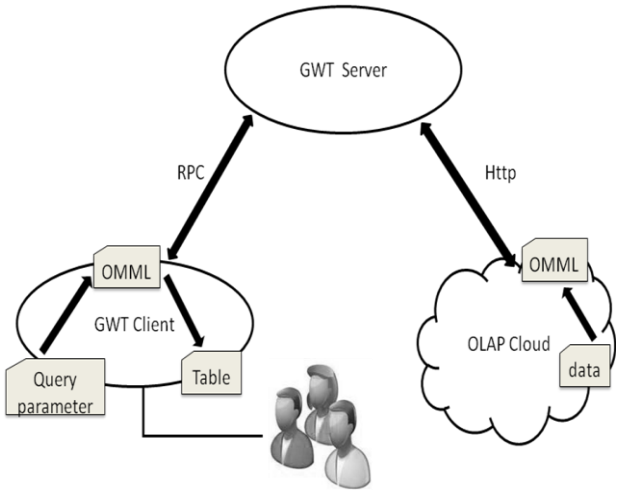

Figure 5. Data flow of the OLAP Query Client

In the service tier, the Elastic OLAP Cloud Platform handles the query sent by the OLAP Query Client, and performs OLAP analysis accordingly. After the analytical result is available, it will be converted into the OMML document. The result will be transferred back through the above mentioned two connections: first through HTTP to the GWT server tier and then through the RPC connection to the GWT client tier. Finally, in the GWT client tier, the query result in the OMML format will be parsed again by the parser module and a related table will be built to present it to the OLAP Query Client in the GUI.

B. Data flow of the OLAP Administrator

Figure 5 presents the data flow of the OLAP Administrator in the multi-tier architecture. Firstly, the OLAP Administrator can initiate a request for accessing the raw data in the Administrator GUI, the request will be sent to the GWT server tier through the RPC connection. After that, based on the OLAP Administrator's specification, in case the requested raw data is provided by a Derby database directly, the Database Access Servlet in the GWT server tier will establish a JDBC connection to the Derby database and forward the request through the connection. When the requested raw data is provided by the OGSA-DAI server, the OGSA-DAI Access Servlet will forward the request through HTTP to the OGSA-DAI server.

OGSA-DAI uses a document oriented interface to support interaction with data sources. Our client system does not need to directly interact with data sources, but send document to the OGSA-DAI data service resource which is associated with a back end data source (e.g. relational database). The document sent to the OGSA-DAI data service resource contains SQL query statement to retrieve the data, besides it could also contain activity specifications to enable some data processing activity on the OGSA-DAI server as preprocessor for the query result data. The document will be parsed and the described action will be performed. The result from databases is generated firstly as a ResultSet Object, then, the ResultSet Object will be converted by the data service resource to generate result document, which is returned through the data service back to the client system.

After the requested raw data sent back to the GWT server tier, the data will be converted into the WebRowSet XML format before returning to the GWT client tier.

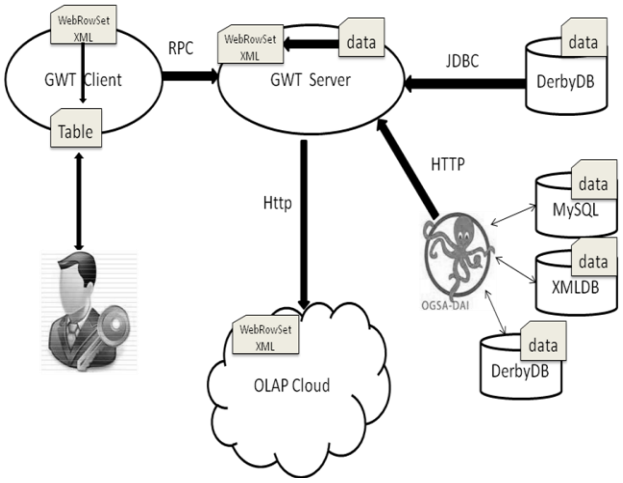

Figure 6. Data flow of the OLAP Administrator

In the GWT client tier, the returned WebRowSet XML data will be parsed by the WebRowSet XML parser module and will be interpreted and presented in a grid table in the Administrator GUI. At this point the OLAP Administrator can check the data and decide if the data are to be loaded into the Elastic OLAP Cloud Platform. If the OLAP Administrator thinks the data is not proper, he can also make some adjustment on the request and get raw data again from the database or the OGSA-DAI server.

VI. GUI SCREENSHOTS

The screenshot of the OLAP Query Client GUI is illustrated in Figure 7.

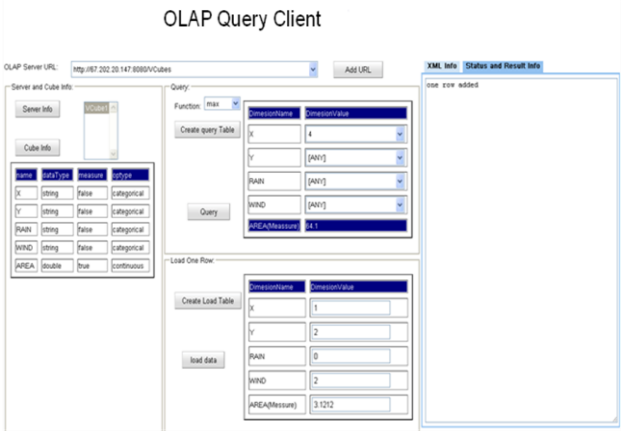

Figure 7. Screenshot of the OLAP Query Client GUI

The screenshot of the OLAP Administrator GUI is shown in Figure 8.

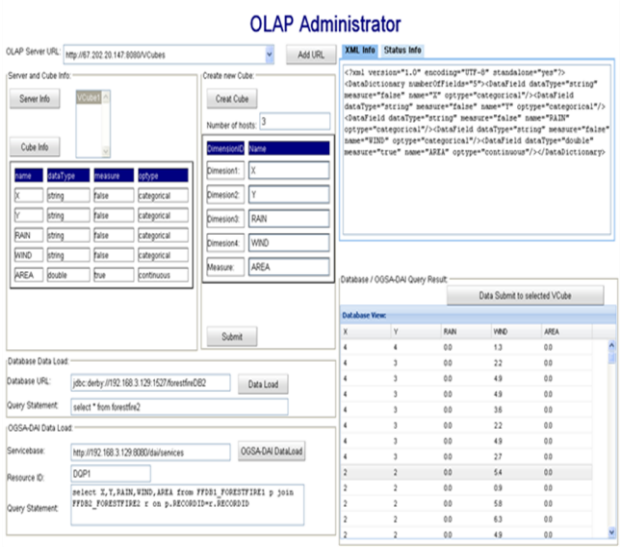

Figure 8. Screenshot of the OLAP Administrator GUI

VII. CONLUSION AND FUTURE WORK

When comparing with computational models from the past, Cloud Computing moves most of the computational work from the user's terminal to the data centers. A Cloud Computing application provides its business logics through well-defined Web Services, which can be consumed by cloud clients. In most cases a cloud client is a Web-based presentation of scalable cloud services and any installation of the client is not required. This in turn allows the end user to obtain superb compute performance and unlimited storage space without huge investments in the local machines. The client system described in this paper is a set of typical cloud clients; it provides a loosely coupled multi-tier architecture for accessing and steering the Elastic OLAP Cloud Platform. Our contribution covers the following main aspects:

- Introduction of the multi-tier client system architecture, which on the one hand accesses and steers the Elastic OLAP Cloud Platform, on the other hand accesses heterogeneous data sources through the OGSA-DAI middleware.
- Extension and further development of the OMML specification as a standard representation of the data cubes, OLAP queries and analytical results.
- Implementation of the proposed architecture.

As the future work, we plan to introduce additional types of data sources at the service tier of the architecture, e.g. real-time stream data from a sensor network. Besides, the client system will be extended according to the planed data-mining extension functionality of the Elastic OLAP Cloud Platform by an approach, which we call as On-Line Analytical Elastic Mining.

***Abstract*—The problem of integer factorization is of high practical importance because of the widespread use of public key cryptosystems for encryption and authentication of Internet connections. In this paper we describe our implementation of the elliptic curve method of integer factorization on an NVIDIA GPU-based cluster using the CUDA technology and report the results of our experiments. The performance of our implementation is compared with other known experiments and software.**

I. Introduction

The elliptic-curve method (ECM) of factorization was introduced by Lenstra in [10]. It can be considered as a generalization of Pollard's $p-1$ and Williams' $p+1$ methods. In the following years much efforts were spent to improve the ECM by proposing more suitable curves and forms of group operations on curve points. The reader can find a detailed description of the development of the ECM and rich bibliography in [14]. We will only mention Montgomery's paper [11], where the Montgomery's form of elliptic curves is introduced.

In recent years new curves and corresponding group laws have been proposed (e.g. [9], [2], [4], see also [1]). Substantial efforts were dedicated to speed the algorithms using hyperelliptic curves, too.

The main advantage of the ECM is that it enables many curves to be used in parallel. That is why the ECM integer factorization is amenable to implementation on multiprocessor and multi-core computer architectures.

Graphics processing units (GPUs) are computation platforms that assure high throughput through massive parallelism. Hundreds and even thousands of threads in the newest hardware, are running in parallel at clock frequencies which are similar to that of CPUs. It makes GPUs suitable for solving problems that possess inherent parallelism. In partial GPUs platforms are suitable for software implementations of algorithms of the number theory and cryptography (e.g. [5] [6]).

When GPU-enabled servers are interconnected in a clustered environment, we have the possibility of combining the fine-grain parallelism of the GPU with the Message Passing Interface (MPI) [8], [12], in order to achieve coordinated execution of the computations. Numerical experiments in this paper were performed on our GPU cluster containing four computing nodes. At each computing node Centos version 5.5 is running on Intel Core i7 processor at 2.66 GHz and 12 GB RAM. The nodes are equipped with a GPU card NVIDIA GTX 295, which is a dual card, i.e., it is visible to the operating system and CUDA as 2 separate graphical devices. Since one card has two devices with 240 computing cores each, we have a total number of 1920 execution threads. The computing nodes are connected via Gigabit Ethernet, which is a limitation and requires a well-chosen communication pattern.

Additionally, some experiments were preformed on an HP ProLiant SL390s G7 server equipped with four GPU cards NVIDIA Tesla M2090 and an Intel Xeon E5649 processor at 2.53 GHz and 96 GB RAM.

II. Preliminaries.

Let N be an integer. Consider elliptic curves of degree 3 in the projective plane over the ring $\mathbb{Z}_N$ of integers modulo N. Lenstra's method uses curves presented in short Weierstrass form

$$y^2z = x^3 + axz^2 + bz^3, \tag{1}$$

where $a, b \in \mathbb{Z}_N$, such that $4a^3 + 27b^2$ is invertible in $\mathbb{Z}_N$, $(N, 6) = 1$.

The Montgomery form [11] of curves is given by

$$BY^2Z = X^3 + AX^2Z + XZ^2, \tag{2}$$

where $A, B \in \mathbb{Z}_N$, such that $B(A^2-4)$ is an invertible element of $\mathbb{Z}_N$. The points $(X : Y : Z)$ on the curve form an additive abelian group with neutral element $\mathcal{O} = (0 : 1 : 0)$ and group operation described as follows. In order to calculate $nP = (X_n : Y_n : Z_n)$ starting with $P = (X_1 : Y_1 : Z_1)$, we use the formulas:

Doubling:

$$d = \frac{A+2}{4};\ s = (X_n+Z_n)^2,\ r = (X_n-Z_n)^2,\ t = d(s-r)+r,$$

$$X_{2n} = sr, \quad Z_{2n} = (s-r)t.$$

Adding (To calculate $(m+n)P$ we need mP, nP, and $(m-n)P$.):

$$u = (X_m + Z_m)(X_n - Z_n),\ v = (X_m - Z_m)(X_n + Z_n),$$

$$w = (u+v)^2,\ t = (u-v)^2,$$

$$X_{m+n} = Z_{m-n}w, \qquad Z_{m+n} = X_{m-n}t.$$

The additive inverse of $Q = (X : Y : Z)$ is the point $-Q = (X : -Y : Z)$ but there is no distinction between these points in the above formulas.

In our implementation we use only addition with $m-n=1$, that is $X_{m-n}=X_1$ and $Z_{m-n}=Z_1$. The start point is $P=(c::1)$, where c is an input value or it is chosen randomly by the software.

Note that

$$4^{-1}(\mathrm{mod}\ N)=\begin{cases}\frac{N+1}{4}, & \text{if } N\equiv 3 \pmod N\\ N-\frac{N-1}{4}, & \text{if } N\equiv 1 \pmod N\end{cases}.$$

Hence, the increasing of A by 1 is equivalent to increasing d with 4^{-1} modulo N.

Suyama's parametrization method described below generates curves whose group of points has a prescribed small divisor. Heuristics show that larger torsion of the curve implies a greater probability that the number of points is divisible of primes less then a given bound, that is, such curve is more "successful". The method is as follows. Take randomly $\sigma>5$ and compute (modulo N):

$$u=\sigma^2-5,\quad v=4\sigma;\qquad A=\frac{(v-u)^3(3u+v)}{4u^3v}-2,$$

$$P=(X_1:Y_1:Z_1),\ \text{where}\quad X_1=u^3,\ Z_1=v^3.$$

With such defined A, X_1, and Z_1 we can take $B=u/Z_1=u/v^3$ and $Y_1=(\sigma^2-1)(\sigma^2-25)(\sigma^4-25)$, but we do not need these values. To calculate $nP=(X_n:Y_n:Z_n)$ we use only X_n and Z_n.

The factorization algorithm consists of two phases.

The first phase:

The point $Q=sP$ is computed, where s is the product of all powers of primes $p^k\le B_1$. Then the coordinates X_Q and Z_Q are tested for having a nontrivial common divisor with N.

Usually the procedure of computing sP is the following. Let $s=(b_kb_{k-1}\dots b_1)_2$ have k bits in binary format, where the first bit is the least significant bit. Starting with b_{k-1} every bit is check if it is 0 or 1. If $b_{k-1}=1$ from the start pair $(P,2P)$ we compute $(3P,4P)$, otherwise $(2P,3P)$. Continuing in this manner for $j=k-2,\dots,1$ we compute

$$\text{if}\ \ b_j=1:\ \ (L,R)\to(L+R,2R),$$

$$\text{if}\ \ b_j=0:\ \ (L,R)\to(2L,L+R).$$

In our implementation this procedure is slightly changed (see section III).

The second phase:

In the second phase of the algorithm for all primes $B_1<p\le B_2$, points pQ are computed. For each point pQ the program check if the coordinates X_{pQ} and Z_{pQ} have nontrivial common divisor with N. The constants B_1 and B_2 are chosen according to size of the expected prime divisors of N. They are defined in the beginning of the program as input constants or automatically by the software. A variant of realization of the second phase procedure is to transform the curve into short Weierstrass form by the following formulas:

$$x=\frac{X}{B}+\frac{A}{3B},\ y=\frac{Y}{B};\quad a=\frac{3-A^2}{3B^2},\ b=\frac{2A^3-9A}{27B^3}.$$

In Weierstrass form the point calculation process requires the use of the extended Euclid algorithm (to invert a number modulo N). This slow up the performance of the algorithm, but increases the probability of finding a divisor of N.

Besides the described above second phase procedure we implement another variant which uses only doubling operation (see the next section).

III. Implementation

Our implementation is based on a branch of the GMP-ECM project (revision 1683) - an ECM implementation based on the GNU Multiple Precision Arithmetic Library. The branch is currently under active development and its target architectures are GPU devices [16]. We enhance the original implementation by using Message Passing Interface (MPI). The communication model chosen is the master-slave model. Our approach to this classical communication model differs from the standard implementations. While most implementations of the master-slave model require the master to take an equal part in the computations and do additional tasks like preprocessing, postprocessing and distributing, we have chosen to separate the master process from the greatest part of the computations. We charge the master only with processing of input, small parts of preprocessing and postprocessing, as well as with distribution of tasks and overall management of the slave processes. Thus the master process has no access to any of the GPU devices and does a minimal part of the computations related to the actual factorization.

The main task of the master is the partitioning and distribution of the computations. In the GPU-based implementation of GMP-ECM all of the curves are pregenerated and the number of curves computed simultaneously depends on the computational capability of the GPU. In our implementation the master distributes the curves in small parts, based on the computational capabilities of the slaves' GPUs, so that the curves in each part can be simultaneously processed by the given slave process. On the other hand, each slave process is associated with a single GPU device and it is called multiple times with different curves. An immediate benefit of this implementation is that it can handle efficiently GPUs with different number of computing cores as the master process takes into account the computational capabilities of each slave's GPU. But note that the use of heterogeneous resources with acceptable load balancing requires relatively larger total number of curves, substantially greater than the total number of execution threads.

In our implementation the slaves work asynchronously. In one communication exchange the master first receives from a given slave process the results obtained after processing a block of curves and then it sends more work to that given process. The master sends the computational tasks using non-blocking MPI calls, thus increasing the speed with which the

master processes the results from the slaves. This approach is effective when the GPUs are with different clock speeds.

Using MPI with GPU devices bears some computational overhead. In the original GPU implementation of GMP-ECM all communications are between CPU and GPU. Since GPUs in a clustered environment cannot currently communicate with each other, in our implementation all of the input that a GPU device receives and all of the results it generates are communicated once between the slave CPU and GPU and once between the slave CPU and the master CPU. Additionally, when using multiple GPU devices on a single host, each slave process needs to explicitly specify the device it will use in order to avoid the situation in which multiple processes are mapped to a single GPU. The process of setting a device varies. In the presented numeric results we have not considered the overhead of setting the device, because we consider it preprocessing.

Because of the asynchronous manner in which the slaves work a small additional overhead to the performance is added during the first communication exchanges. This overhead manifests mainly when the number of curves is equal or slightly greater than the total number of execution threads in the system. As the number of curves increases the slowdown becomes more and more negligible.

In our implementation we chose to completely separate the GPU-related code and MPI code. Because of this we have chosen to use the C implementation of MPI and compile the MPI code using a C compiler, while the CUDA code is compiled using the NVIDIA C++ compiler for CUDA [7]. This approach takes full advantage of the fact that MPI and CUDA are orthogonal and naturally allows each part of the code to be treated separately, thus making modifications and fine-tunning of our implementation easy.

Some features of our software which concern the implemented algorithm are the following:

Our software implementation enables computations with Montgomery curves parameterized in two manner:

- "Standard"parametrization: We start with an initial point $P = (c : : 1)$, where c is an input value or it is chosen randomly by the software. Starting with a given d_1 (input parameter or randomly chosen) we compute $d_2,\ d_3,\ d_4$ by adding $4^{-1} \pmod N$. Then enlarge the set $\{d_1, d_2, d_3, d_4\}$ by adding 1 to each element until we obtain the numbers of parameters d equals to the number of threads.
- Suyama's parametrization: For each thread we generate a random σ and precompute the parameters $u,\ v,\ A$, and the initial point $P = (u^3 : : v^3)$.

In phase one we first compute $Q_1 = s_1 P$ by the method described in Section II, where $s = 2^l s_1$, s_1 is odd. Then we compute $Q = 2^l Q_1 = sP$ only by doubling points.
We assign different value of A (indeed of d) for each thread. This assignment is realized in the described above manner.

In phase two we implement the classical algorithm (as it is described at the end of Section II) as well as a variant that consists of only doubling Q (or several pQ). In the latter case we collect the product of Z coordinates in a variable PROD_Z and periodically check its greatest common divisor with N.

Our experiments show that the second form of the phase two gives commensurable results with very good performance.

IV. Numerical experiments

Table I and the three figures represent the results of our numerical experiments. The tests are performed on the NVIDIA GTX 295-based GPU cluster. In the test cases the number of threads per block is effectively 512. Tests were performed with two implementations of MPI - Open MPI v1.4 and Intel MPI v4.0.3 and a negligible speedup was observed when using Intel MPI. In terms of parallel efficiency, our application showed excellent results with lowest efficiency of over 97% for 8 GPUs.

Additional experiments were performed with the original GPU implementation of GMP-ECM on a greatly superior

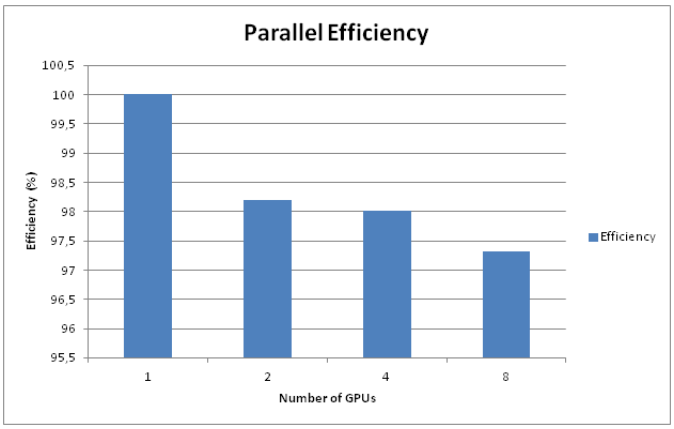

Fig. 3. Parallel efficiency.

GPU - NVIDIA Tesla M2090. This card is equipped with 512 CUDA parallel processing cores, delivers 665 GigaFLOPS of peak double-precision performance and 1331 GigaFLOPS of peak single precision performance. The memory bandwidth is 177 GB/sec with ECC turned off. The results were compared to those of the older NVIDIA GTX 295 and showed that the acceleration is proportional to the ratio between the peak processing powers for single precision operations of both GPUs, where M2090 is around 1.3 times faster. While GTX 295 is a gaming card that has ratio of single to double precision of 8 to 1, M2090 has much better ratio of 2 to 1. The relatively small difference is explained by the fact that the application uses only integer operations, which makes GPUs with lesser processing power for double precision operations a suitable and inexpensive choice for such problems.

V. Conclusions and Future Work

The parallel implementation of the GMP-ECM using our GPU cluster demonstrated excellent parallel efficiency using the master-slave paradigm, which is not limited to homogeneous resources. This scalability is achieved when using large number of curves, proportionate to the total number of cores in the distributed system. Further improvement of the chosen communication pattern is required to minimize the loss caused by the message passing between the master process and the slave process. Our implementation is independent of the concrete types of General-purpose computing on GPU (GPGPU) cards involved in the computation. Since in practice only a limited number of different cards can be involved in a given computation, a hybrid approach that organizes the GPGPU cards in blocks consisting of homogeneous resources may be considered. Some of the stages of the computations can also be shortened at the expense of more frequent communications, which opens the question of finding the right balance. Additionally a part of the postprocessing that is currently done on the master process may be transferred to the slaves, thus allowing the master to work more efficiently with a large number of slaves. In some practical situations where the researcher does not have full control of the infrastructure available, it may not be possible to interconnect all the resources with the same version of MPI. This motivates our work on a different parallelization approach that uses lower-level communication over UDP.

An I/O Cost Optimal and Progressive Algorithm for Computing Massive Skyline Points

Mohammadmehdi Talebi* and Mohammadreza Razzazi*
*Amirkabir University Of Technology/Department Of Computer Engineering and IT,Tehran, Iran
mehdi_talebi@aut.ac.ir, razzazi@aut.ac.ir

Abstract- **We describe an I/O cost optimal algorithm for computing skyline points among a set of d-dimensional points. In this paper we develop Partitioning, a progressive algorithm based on branch and bound search. It computes the skyline points in a progressive way that is outputting results while the algorithm is running. Our progressive (or online) algorithm can quickly return the first skyline point, without having to read the entire data file, this property is important in the database community.**

When there are numerous skyline points, an important issue is the amount of memory used during the execution, which is reduced in this paper.

There is also a current tendency towards addressing problems in a distributed manner, to enable decentralization and faster computation. If the data sets are very large, significant retrieval speedups can be obtained via parallelism. Since we used R-tree for indexing data points, so a version of parallel distributed R-tree architecture can be used for distributed environments.

***Index Terms*— I/O cost, Maxima, Query, Spatial databases, Skyline.**

I. INTRODUCTION

In this paper, we consider one of the basic problems in computational geometry of computing the maxima (later called skyline) of point sets in d-dimensional space. Given two points *p* and *q*, the point q is said to *b*e dominated by the point p iff the coordinates of p are larger than the coordinates of *q* in all dimensions. Point *p* is said to be a *maximal point* of a set of points *P* iff it is not dominated by any other points in *P*. The union MAX*(P)* of all points in *P* that are maximal is called the *set of maxima* of *P*.

The problem of finding all maximal vectors in a set of n d-dimensional points is first studied by Kung, Luccio, and preparata [1]; Bentley and Kung [2] show that the average number of maxima points in a set of n d-dimension vectors is $O((\ln n)^{d-1})$, they suppose that points are distributing uniformly. Previous algorithms for computing maxima points are not I/O cost efficient, especially when the number of maxima set is O (n). Obviously, in higher dimensions, the number of maxima points increases and causes unacceptable I/O cost. Space-efficient solutions for fundamental algorithmic problems such as queries in spatial databases, merging, sorting or partitioning have been studied for a long time; see [5], [7], [12], [13] and [14].

In spatial databases points are stored in disk, suppose that there are 1M points stored, according to [2], there must be approximately 16 maxima points (experimental results in [23] reported 120 points); but if for these 16 points we load all of the 1M points in the main memory, it will be costly. You should notice that CPU executes instruction in nanosecond scale while disk, loads files in millisecond scale. Therefore, I/O cost can be very expensive. Our partitioning algorithm computes the maxima points such that its I/O cost is efficient. The maxima problem has been actively investigated in the database community following Börzsönyi, Kossmann, and Stocker's definition of the SQL "skyline" operator [18]. Since I/O cost is our main interest in this paper we use the same notion of skyline operator. You should notice that skyline operator computes points under this concept that "the smaller is the better" which means that point p dominates point q iff p is smaller than q in its dimension.

II. Related Works

Finding skyline of a set of points is useful in a variety of applications in economics, statistics, and operations research (as noted by Preparata and Shamos [4]), and thus was among the fundamental problems studied in computational geometry. In [3], authors examine the expected complexity of boundary problems on a set of *N* points in *d*-space. They present an algorithm to find the maximal points using $dN + O(N^{1-1/d} \log^{1/d} N)$ expected comparisons. A lower bound shows that the algorithm is optimal. In two and three dimensions, the best known algorithm which has been developed by Kung, Luccio, and Preparata [1] identifies the set of skyline points in $O(n \log n)$ time which is optimal since the problem exhibits a sorting lower bound [1], [4]. For dimension $d \geq 4$, their divide-and-conquer approach yields an algorithm with $O(n(logn)^{d-2})$ running time. Matoušek [9] gave an $O(n^{2.688})$ algorithm for the case $d = n$. The problem has also been studied for dynamic environments in which there are changing point sets and assuming that the input points are distributed in higher dimensions [10] ,[15] and [16].

Computing skyline points has been actively investigated in the database community following Börzsönyi, Kossmann, and Stocker's definition of the SQL "skyline" operator [18].

Figure 2. Steps for BBS.

Börzsönyi et al. [18] noted that such an operator producing the set of maxima is needed in spatial databases, in some queries, such as asking for hotels that are close to the beach and cheap. In spatial databases, I/O cost is important, it is also very critical to propose an algorithm that computes the skyline points in a progressive way that is outputting results while the algorithm is running [6], [11], [17], [19] and [20].

A straightforward approach to compute the skyline is to compare each point p with every other point; if p is not dominated, then it is a part of the skyline. Block Nested Loop (BNL) [18] builds on this concept by scanning the data file and keeping a list of candidate skyline points in main memory.

In [20], the authors use Divide and Conquer approach, their algorithm (D&C) divides the dataset into several partitions so that each partition fits in memory. Then, the partial skyline of the points in every partition is computed using a main-memory algorithm (e.g., [21]), and the final skyline is computed by merging the partial ones.

Reference [19] presents an algorithm using Nearest Neighbor to compute the skyline points, their algorithm (NN) uses the results of nearest neighbor search to partition the data universe recursively and find the maxima set.

III. Our Algorithm

Our partitioning algorithm computes skyline points such that I/O cost is optimal. We use R-tree (tree data structures used for spatial access methods, i.e., for indexing multi-dimensional information such as geographical coordinates, rectangles or polygons) for indexing data points. For the following discussion, we use 2D data points of Figure 1, organized in an R with node capacity 3.

Obviously, skyline set in Figure 1 is {a,b,c,d,e,f,g,h}. Intermediate entries denoted by e_i , are the Minimum Bounding Rectangles (MBR) of nodes N_i in each level, while each entry introduces a new data point. For each data point, dist is the summation of its coordinates, and the dist of an MBR equals the dist of the lower-left corner point of the rectangle. For an MBR e, e.corner denotes its lower-left point.

BBS [23] is an I/O cost optimal algorithm for computing skyline points. It starts from the root of the tree and inserts e_5, e_6 *and* e_7 in a heap, sorted according to their dist. Then the entry with minimum dist is picked up for expansion.

Entry e_5 is removed from the heap and entries e_1 , e_2 *and* k are inserted into the heap. Next entry with minimum dist is e_6, so after expansion it is removed and entries e_3 , e_4 *and* n are inserted into the heap. Figure 2 shows the procedure up to step 8. Each entry is inserted into heap by its dist. In step 6 data points c, d and j are inserted, and finally in step 7, b is chosen as the first skyline point, and is added into the set S (set of skyline points). When S is not empty and an entry is expanded from heap, among its children, the only ones which are not dominated by any points in S are inserted into heap. We can prune e_7 because $e_7.corner$ is dominated by some points in S.

There are some problems; the first one is the number of skyline points. When $|S|$ is $O(n)$, then the cost of dominance checking for all of the data points in S will be costly. Especially, when the points in S are not stored in main memory. Even if the points in S are stored in main memory, the number of dominance checking will be high and affects the cost of the computing.

Another problem is the number of entries stored in To-Do list. In this paper we handle these two problems.

IV. Dominance Checking

Assume $S = \{s_1, s_2, s_3, \dots, s_k\}$ is a set of existing skyline points and a new point p is a candidate to be a new one. By lemma1 p can't dominate any point in S because $s_i.dist \leq p.dist \quad \forall s_i \in S$.

Lemma1. *In a d-dimensional space for two points p and q, if* $p.dist \leq q.dist$ *then q doesn't dominate p.*

Proof. *Immediate.*

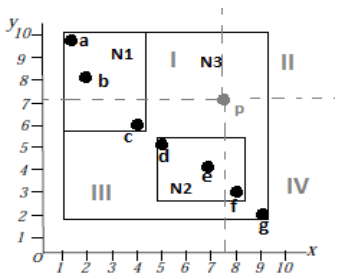

Figure 3. Dominance range query for point p.

```
bool Function Dominate (node e, R-tree S)
1.insert all entries of the root S in the Queue
2.while Queue is not empty
3.  remove top entry s
4.  if s is a data point inside dominance region of e
5.        return true
6.  else
7.    if s is fully inside the dominance region of e.corner
8.        return true
9.    else if the SSR region of e.corner contains
          at least one hyper plane of s
10.           return true //lemma2
11.  else sort children of s according to their
       dist in descending order
12.     for each child si of s//si.dist is the biggest one
13.       if si satisfies lemma 2
14.          return true
15        else if si.corner is inside the SSR of e.corner
16.          insert ei into Queue
17. end while
18. return false
```

Figure 4. Dominate Function.

Now, we must check data point p with the points in S for domination test. One easy way to determine is to compare the new point with all of the points in S, but we introduce another method. We use a type of Range Query for dominance checking which is called dominance query in this paper.

Suppose points in Figure 3 as existing skyline points determined up to now and p is a new one. Due to the definition of domination, we have four regions (I, II, III, IV).

Point p dominates all points in region II, called Dominance Region (DR), and is dominated by all of the points in region III, called Skyline Search Region (SSR).

So for dominance checking, we do a range query in region III, if there is any point inside, point p is pruned (not considered as a skyline point) and if the range query reported the region empty, then point p is identified as skyline.

Range queries have different applications in GIS systems and spatial databases. A range query retrieves all data objects lying inside or intersecting a multi dimensional hyper-rectangle. Sometimes users need only summarized information about the data objects instead of each one's properties. There are some range queries for such needs, called aggregate range queries [24] and [25], which return only a single value according to the aggregate function, like the average of points. Distributive aggregates (e.g., count, max, min, sum) can be computed by partitioning the space, in each sub space, we can continue the computing recursively.

In this paper, we use a type of aggregate range query that just checks the existence of a data object in a multi dimensional hyper-rectangle. In Figure 3, region III is the multi dimensional hyper-rectangle that we must check the existence of a data object.

We index skyline points by R-tree and apply the dominance query by using it. For example in Figure 3, obviously e_3 is expanded and among its children, e_1 *and* e_2 are checked. Obviously if one of the children, was fully inside dominance query, then we could stop searching and say there exist at least one data point in our searching region. But, here, nodes e_1 and e_2 are not fully inside our dominance query so we must continue our search, in next step, node e_1 is expanded, and point c is found, which indicates point p is dominated. By lemma2, we make our dominance range query faster.

Lemma2. *If a hyper plane of an intermediate node is fully inside the dominance query, we can stop search procedure and claim that there exists at least one point in our searching region.*

Proof. *Notice that in an R-tree all of the 2*d hyper planes which are the borders of the hyper cube related to an intermediate node are tangent with at least one data point.*

In Figure 4, the pseudo code of *Dominate* function is presented. S is the root of the R-tree related to the existing skyline points. In line 9, according to lemma2, we check whether SSR region of e contains any hyper plane of entry s or not. In line 11, if s doesn`t satisfy lemma2, it is expanded. Children are sorted according to their corners in descending order, child with maximum corner is picked up, and if it satisfies lemma2, then true is returned; else if its corner is inside the related hyper rectangle, then is inserted into the Queue.

V. Reducing to-do list length

Obviously, when there are numerous skyline points, there will be so many intermediate nodes or data points in our To-Do list (e.g. in Figure 2, up to step 8, most of the entries are inserted into the To-Do list, while no skyline point is found).

Our partitioning algorithm discovers the space in depth-first order. We explain our new strategy by R-tree presented in Figure 1. We first push e5, e6 and e7 into a stack, then we expand e5 due to its minimum dist, so e1, e2 and k are inserted into the stack, in BBS e_6 is expanded in the next step, but here we choose an entry among the children of e5 (e1,e2,k) and choose the one with minimum dist (e.g. e1). So in next step we expand e1 and insert a, b and i. Up to here, stack includes {e7, e6, k, e2, i, a, b}. The steps of the algorithm are presented in figure 6. Each time we expand one intermediate node, its children are sorted according to their dist, and checked for domination (which we explain later). After dominance checking, we push them into the stack in descending order and each time, we just pop the first entry from the stack for expansion. In this way, we search the R-tree in depth-first order.

Every time a new entry is picked up, a dominance checking is done. In partitioning (presented in Figure 7.), when we check S for domination, still we can`t be sure that this new entry can't be dominated later. Notice that contrary to BBS we don`t access entries according to their dist in ascending order. We must do a domination test among the entries in to-do list. Since the size of our To-Do list is kept small (later we discuss about the size of the to-do list) so this checking is not costly.

```
int  Function ToDoListDominate (node e, link list L)
1. current = L.first
2.  num =2
3. if ( current = = NULL)
4.      return num
   DO
5.    if ( e is inside the dominance region of current)
6.         discard current
7.    else if (dominance query of e.corner intersects
            current)
8.       {
9.         num  = 3
10.          if  one of the current.hyper planes is fully
                inside e. dominance query  //lemma 2
11.             return 1
12.         else
13.              NewParent = current
14.       }
15.    current = current.next
16. While current != null
17.if   num = = 3
18.      insert current into NewParent as a virtual
          Child.
19. return num
```

Figure 5. ToDoListDominate Function.

For each candidate entry that we want to insert, a dominance checking is held, like Figure 3. But we do such checking among the entries in the link list, and if it is dominated, then will be pruned.

Lemma3. *If a dominance query is held by a point q, and one intermediate node e is intersected by that without satisfying lemma 2 then q is inside e.*

Proof. *Immediate.*

Dominance checking for an entry, includes three states. In Figure 5 we illustrate these states by the number returned by function *ToDoListDominate*. If the number returned is 1, it means that the entire entry is dominated by some point or entry in the To-Do list and must be pruned. If num is 2, it means that the entry can`t be pruned because none of the entries in the To-Do list dominates the entry. If num is 3, it means that the query related to the node e intersects some nodes in the To-Do list, but lemma2 is not satisfied (e.g. the source of the query is inside those nodes (lemma3)).

If one node intersects an intermediate node without satisfying lemma2 (e.g. Q), it will be removed because later (when Q is expanded) this node will be accessed again. Notice that we virtually insert the entry into that node (e.g. Q). By virtually we mean that, this insertion is not like the insertion of R-tree. We assume that each node of the To-Do List consists of two parts, the first part includes an entry of the R-tree and the other part is a link list presenting the virtual children. Notice that we do a virtual insertion if there is not any other entry or point dominating this new entry or point in the To-Do list.

VI. Analysis

In Figure 8, there are four points as existing skyline points. The space is divided into two subspaces. Obviously, any entry in region II is dominated by one of the skyline points. So, if we want to expand one entry, we make sure its corner is inside region I (SR). We prove that the nodes not intersecting SR are not expanded, and finally we discuss about the I/O cost. First we discuss about the correctness of the partitioning algorithm.

Lemma4. *If any data point p is added into skyline points during the execution of the algorithm then it is guaranteed to be a final skyline point.*

Proof. *Before identifying any data point as a skyline point, we do a dominance checking. By function Dominate we check existing skyline points and by function ToDoListDominate we check To-Do list, so if a data point p is not dominated by any point, it can be considered as skyline. You should Notice that the points which will be added into existing skyline set later, are kept in To-Do list*

Lemma 5. *Any data point will be examined, unless one of its ancestor nodes has been pruned.*

Proof. *When an entry is picked up from To-Do list, it will be expanded unless being dominated by some points in existing skyline points or in To-Do list.*

Lemma 6. *Partitioning visits all of the entries of the R-tree unless they are dominated by some points in existing skyline or entries in To-Do list.*

Proof . *Immediate by lamma5.*

Lemmas 4, 5 and 6 guarantee the correctness of the Partitioning algorithm.

An important issue regards the dominance checking, which can be expensive if the skyline contains numerous points. In order to speed up this process, we index existing skyline points in a main memory R-tree, so by function

#	Action	To-Do List	S
1	access root	$(e_5, 6)$ $(e_6, 7.5)$ $(e_7, 17.5)$	$\emptyset$
2	Expand e_5	$(e_1, 9)$ $(e_2, 9)(k, 15)$ $(e_6, 7.5)$ $(e_7, 17.5)$	$\emptyset$
3	Expand e_1	$(b, 10)(a, 11)(i, 14)(e_2, 9)$ $(k, 15)$ $(e_6, 7.5)(e_7, 17.5)$	$\emptyset$
4-6	b,a,i skyline?	$(e_2, 9)(k, 15)$ $(e_6, 7.5)(e_7, 17.5)$	$\{a, b\}$
7	Expand e_2	$(c, 10)(d, 10)(j, 11.5)$ $(k, 15)$ $(e_6, 7.5)(e_7, 17.5)$	$\{a, b\}$
8-11	c,d,j,k skyline?	$(e_6, 7.5)(e_7, 17.5)$	{a,b,c,d}
12	Expand e_6	$(e_3, 9)(e_4, 10)(n, 18)(e_7, 17.5)$	{a,b,c,d}
13	Expand e_3	$(e, 11)(f, 11)(l, 13.5)$ $(e_4, 10)(n, 18)(e_7, 17.5)$	{a,b,c,d}
14-16	Are e,f,l Skyline ?	$(e_4, 10)(n, 18)(e_7, 17.5)$	{a,b,c,d, e,f}
17	Expand e_4	$(g, 11)(h, 11)(m, 13.5)$ $(n, 18)(e_7, 17.5)$	{a,b,c,d, e,f,g,h}
18-21	g,h,m,n skyline?	$(e_7, 17.5)$	{a,b,c,d, e,f,g,h}
22	Prune e_7	$\emptyset$	{a,b,c,d, e,f,g,h}

Figure 6. Steps for partitioning.

```
Algorithm Partitioning (R-tree R)
1. S = ∅// R-tree of skyline points
2. insert all entries of the root R in the ToDo stack
3. while ToDo stack is not empty
4.    pop entry e
5.    if ( Dominate (e,S) = = true)
6.       discard e
7.    if e is an intermediate entry
8.       sort children of e according to their dist
9.    for each child ei of e in ascending order.// if e
      //is not an intermediate node then ei is supposed
      //to be a point.
10.      if ( Dominate (ei,S) = = true)
11.         discard ei
         else
12.         num = ToDoListDominate(ei,ToDo))
13.         if ( num = = 1)
14.            discard ei
15.         else if (num = = 2)
16.            if ei is a point push it into S
               otherwise insert ei into ToDO.
17.         else if (num = = 3)
18.               if ei is a point, remove it
19.               if ei is an intermediate node
20.                  discard ei // ei is virtually
   // insered into another node in To-Do list by function
//ToDoListDominate
21.end of for
22. end of while
End Partitioning.
```

Figure 7. Partitioning algorithm.

Dominate we can do dominance checking very fast.

Lemma 7. *If there is no intersection between MBRs of the R-tree then The size of the To-Do list in partitioning algorithm is* $O(f * (log_f^{n/f}))$, *Where f is the fan-out of the R-tree.*

Proof. *In partitioning we discover the space in depth-first order, so in each level at most f entries are inserted into the To-Do list. Since the height of the R-tree is* $O(log_f^{n/f})$, *so the number of entries in To-Do list will be* $(f * (log_f^{n/f}))$.

The cost of the ToDoDominance function is related to the size of the To-Do list. Suppose that there are 10^7 points in space and $f = 10$, therefore, the length of the To-Do list will be 60 which, in comparison to the number of points and intermediate nodes is very small.

Another important issue regarding the dominance checking is the cost of the Dominate function. Each time a new entry is picked up, we must check the entire existing skyline points, which can be expensive if there are numerous number of them. By the use of an R-tree and function Dominate we deal with this problem.

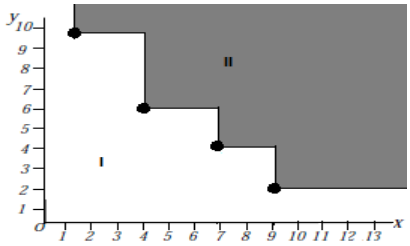

Figure 8. Skyline and dominance regions.

There are several works [26], [27], [28] and [29] which discuss about the cost of the operations on R-tree. In [26], authors present a detailed study about range aggregate queries in spatial databases. Notice that our aggregate range query is not as complicated as the query type presented in [26] because we just want to test the existence of a data point in a range query but not reporting all of them. In [26] it is proved that for a range aggregate query that reports the number of points, the number of node accesses is $O\left(K^{\frac{d-1}{d}} * log_f^{s/f}\right)$, where d is the dimension of space, K is the number of points reported, s is the number of points indexed in an R-tree whose fan-out is f.

You should notice that this is a very pessimistic upper bound because our query (especially supported with lemma2) is very less complicated than query tackled in [26]. In our query, we want to see whether there is any point in a specific region or not, so the worst case time is when the number of points, inside range query is constant ($k \in O(1)$).

Lemma8. *Partitioning accesses all nodes whose MBRs intersect SR.*

Proof. *In partitioning, we insert all intermediate nodes in the To-Do list, except ones that are dominated by some other point, that means we prune those nodes not intersecting SR.*

Lemma9. *Algorithm partitioning expands only nodes that intersect SR.*

Proof. *Suppose node Q doesn`t intersect SSR, so there must be at least one point dominating it. For sure this point will be found by dominance checking.*

Theorem1: *Partitioning algorithm is I/O cost optimal.*

Proof. *By lemma 8 and 9 we proved that partitioning only accesses nodes that may contain skyline points, so we don`t expand an intermediate node that does not contain skyline point (doesn`t intersect SR). Now, suppose an entry e is picked up from To-Do list, if e doesn`t intersect SR, then by lemma 9 we are sure that it will be pruned.*

We end this section by presenting a cost model for the number of node accesses (NA) in our algorithm. We denote the number of node accesses at each level i of R-tree by NA_i.

Let $p_i(\alpha, \beta)$ be the probability that an MBR of level i intersects the rectangle built by (0,0) and (α, β) as opposite corners. Assume $D_i(\alpha, \beta)$ is the node density at level i. Formally $D_i(\alpha, \beta) = \partial^2 p / \partial\alpha\partial\beta$ [27]. Number of node accesses at level-i equals:

$$NA_i = \frac{N}{f^{i+1}} * P_{int-i} \quad \text{and} \quad P_{int-i} = \iint_{(x,y,)\in SR} D_i(x, y)$$

where N is the cardinality of points, f the fan-out and P_{int-i} is the probability that at level i one node intersects SR.

The value $D_i(\alpha, \beta)$ depends on data density at location (α, β) (as analyzed in [27]). Obviously $D_i(\alpha, \beta) = 0$ for every $(\alpha, \beta) \in SR$. You should notice that if there was any point in SR it would have been chosen as a skyline point. We can claim that $D_i(\alpha, \beta)$ is low (but not zero), resulting

small NA_i. The total number of NA is the summation of NA_i at each level.

Suppose that each leaf node visited contains at least one skyline point, number of node accesses in partitioning(NA_{Par}) is below s.h where s is the number of skyline points and h is the height of the R-tree. Therefore NA_{Par} is $O(s * log_f^{n/f})$. For sure this is a pessimistic upper bound because skyline points may be found in the same leaf nodes, which means Partitioning doesn`t access a complete path for each skyline point from root to a leaf.

VII. Conclusion

In most of the algorithms for computing skyline points, there are several problems that make them inapplicable in practice. BNL and D&C [18] and [6] are very sensitive to main memory size. In addition, neither of them is progressive. You should notice that, since in partitioning space is discovered in depth-first order, so first results will be reported very soon.

Algorithm NN [19] is based on nearest neighbor search. Its performance is poor and needs prohibitive space requirements for more than three dimensions.

BBS [23] is an I/O cost optimal algorithm for computing skyline points. But, dominance checking cost can be high and this makes the algorithm sensitive to the main memory size, even if there is enough memory, the performance will be reduced. In BBS a main memory R-tree is used for existing skyline points but instead of indexing points, the dominance region of any point, is indexed.

Since most dominance regions will cover a large part of the data space, so there will be significant overlap between the intermediate nodes which can be costly. In partitioning, we reduced the cost of dominance checking; in addition, we reduced the length of the To-Do list. In BBS when there are numerous skyline points, To-Do list will be too large; but in partitioning, we handled this problem. Our algorithm also reports first skyline point much earlier than BBS, because contrary to BBS, we don`t visit nodes in breadth-first order.

***Abstract*— Due to the message transmission between processes in a distributed system, an error in a process might be propagated to another via faulty messages, which causes a global failure. In the absence of built-in fault detection methods, rollback recovery approach is not useful. To avoid error propagation and rollback overhead, roll-forward recovery schemes based on redundancy techniques such as N-Version Programming techniques have been presented. The disadvantage of using these schemes is that they need to block the receiver process until each received message is confirmed by the other version of the process, which results in high time overhead. In the case of variant response latencies, consisting of processing time and message transmission delay, these techniques would not be efficient. In this paper, a non-blocking roll-forward recovery approach with some changes to duplex system is proposed. This approach does not avoid fault propagation. But it performs an additional test using a copy of a failed module version to discover faulty process and replace its state with the fault-free process and mask the faults which are propagated to other processes; so it does not need to block processing or message transmission in any phases of the process. This scheme has lower execution time than existing roll-forward techniques.**

I. INTRODUCTION

Faults in distributed systems can be categorized base on their behavior, in three category *crash failures*, *omission failures* and *byzantine failures*. In the case of *crash failures*, a faulty process stops executing prematurely, in the case of *omission failures*, faulty process intermittently omits to send or receive messages, and finally in the case of *byzantine failure*, faulty process can exhibit any behavior, it can change its state arbitrarily, send messages with incorrect content [1].

Faults can also be categorized by the phase in which they are introduced: *Design faults* are those which arise during the system design or during modification of system. *Operational faults* are ones which appear during the system lifetime and are caused due to physical reasons e.g. hardware failures or failure of communication network in the system. Generally, design faults are much harder to tolerate than operational faults.

The root cause of failure of hardware components like nodes and links is frequently physical failure. Software, in contrast, has no physical properties; it is a totally conceptual entity. Hence, physical faults cannot exist in software. Software faults are always *design faults.* That is, a fault in the software due to incorrect designs or presence of "bugs", which are usually caused by human errors (in contrast to physical failures, which are caused by natural laws). To build software that can handle faults in its components, we need techniques that can cope with design faults. We will call such software *fault tolerant software* [2].

A system is fault tolerant if it can mask the presence of faults using redundancy. The goal of fault tolerance is to avoid system failure, even if faults are present.

It is clear that only replicating the same component will not help in coping with design faults, because if software has a design fault, then all replicas of the component will also have the same design fault, and hence the fault cannot be masked. To solve this problem the redundant units are intended to compensate for, or mask a failed software unit when they are not affected by software faults that cause similar errors at cross-check points. Therefore each simplex unit in set of units needs to be built separately and independently of the other members of the set. This is the concept of software design diversity

There are many approaches for organizing diverse design to build fault tolerant software. Two main methods are the *recovery block approach* and *N-version programming*. This paper explains that replicating the same component is not always useless. In section 4 we explain that using design diversity and component replication together, makes it possible to distinguish between failed and failure-propagated components [2].

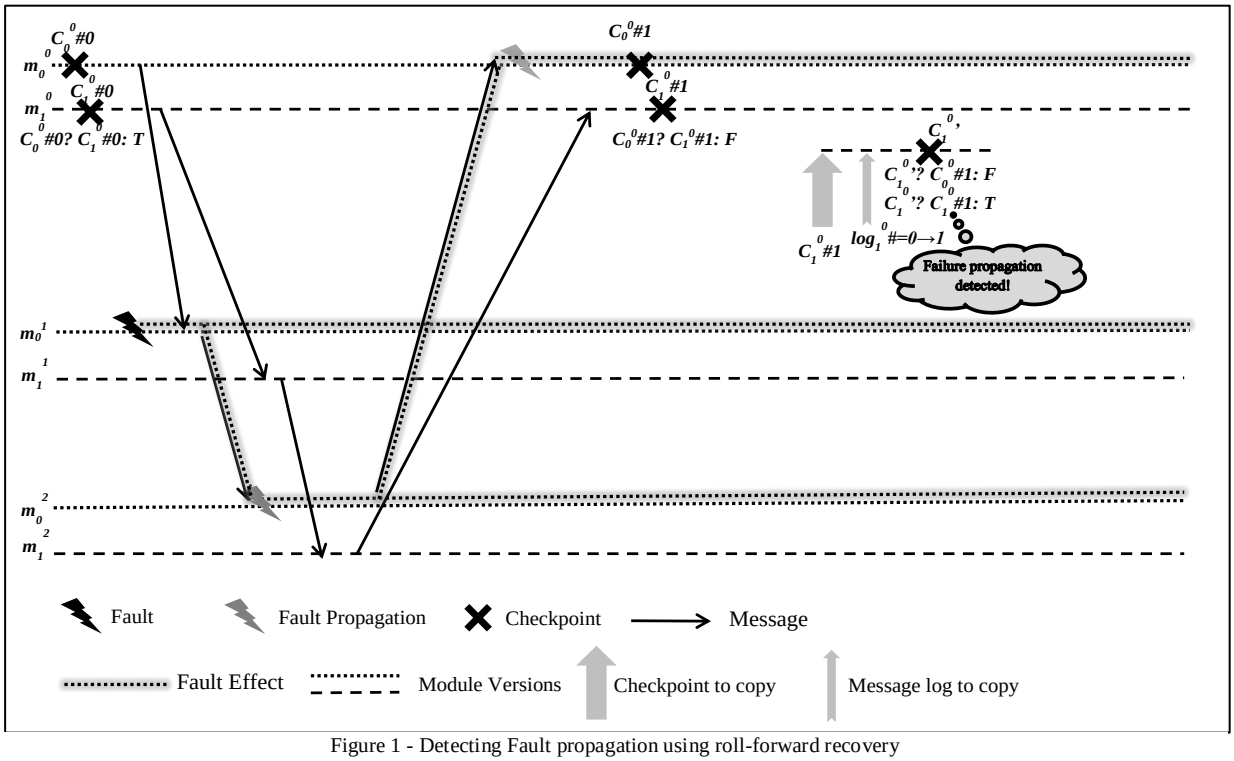

Figure 1 - Detecting Fault propagation using roll-forward recovery

The paper is organized as follows: in section 2 some related works about recovery in message passing systems with fault detection latency is presented. In section 3 the system model and basic assumptions for new protocol are explained. In section 4 our new scheme called non-blocking roll-forward recovery is presented. In section 5 an analysis and comparison about the performance and overhead of new scheme and existing schemes are made, and finally in section 5 the conclusion is presented.

II. Related Works

Tolerating faults in distributed systems is possible in two ways: backward error recovery and forward error recovery. Both approaches use checkpointing to recover the correct state. Authors in [3] assumed that each process uses some reliable fault detection mechanisms that discovers all failures occurred with a finite latency. When a failure is discovered, the failed process sends a message to all processes, and then they compute unsafe (probably unsafe) checkpoints and finally rollback to last safe checkpoint and discard or repeat messages when necessary. Pradhan in [4] proposes to use duplex systems and triple modular redundancy to perform forward error recovery for multiprocessors called *roll-forward recovery* in contrast to *rollback-recovery*, but paper does not consider message passing between processors and error propagation. After that, [5] and [6] extend this approach for message passing systems. Responsive roll-forward recovery method [6] proposed that each message of a version, before any transmission must be confirmed by another version, this approach causes high time overhead in case of variant message response delay. Such delay can exist because of different processing times or different message transmission times. Sobe in [5] propose a new method based on duplex systems that each version sends its message to target versions alternately and information about its next message is piggybacked on that message, this method has time overhead like [6], because receiving process must postpone any message transmission until the received message be confirmed. In this paper our aim is to remove this delay. All of these approaches use checkpointing to save system state and retrieve correct states when necessary. Authors in [7] represent some roll-forward checkpointing scheme and in [8] the previous work has been timely improved.

III. Model and Basic Assumptions

A system is modeled by a number of processes that communicate via sending and receiving messages. Each node contains a running module that performs some tasks in a deterministic way, such that each module received a message, performs some processes on the input message and sends some messages to other nodes. In order to achieve fault tolerance, some redundancy such as module replicas are used to detect and mask failures. Module *a* is called a *version* of module *b* if it performs the same task as *b* but uses modular redundancy, i.e. for each input message, module *a* uses a different source code from module *b* to do generate the same output. Module *c* is called a *copy* of module *d* if it performs the same task as module *d* and also uses the same source code as module *d*. A special processor, called the Checkpoint Processor, is used to save and compare checkpoints and perform recovery when the need arises.

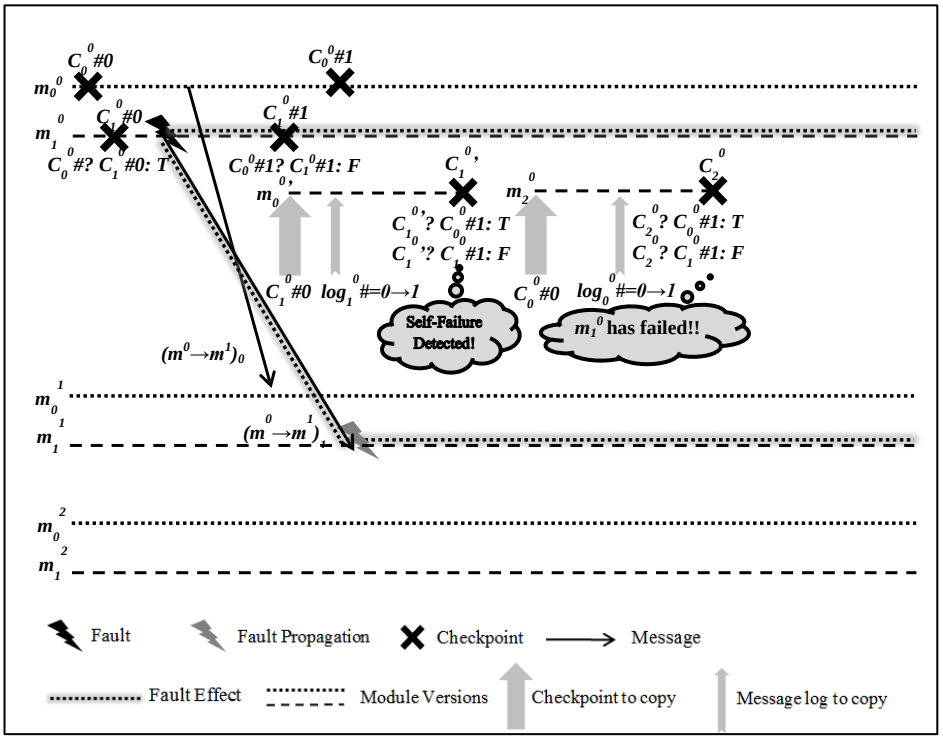

Figure 2-Detecting faulty version

Any module can fail while processing an input message. A failure probably causes no message output, wrong output messages to target nodes, or some additional messages to other nodes. Any wrong message, will lead the receiver node to a failed state and results in some behavior as a failed node.

We assume that hardware is reliable, and then two module copies of a version never behave different from each other due to hardware failure.

IV. New Roll-Forward Protocol for Message Passing Systems

To explain this protocol, replicas of a module *m* is denoted by $m_{i,j}$ which represents the copy *i*th copy of the *j*th version of module *m*.

Assume a message passing system consists of *n* modules $M=\{m^0,m^1,...,m^{n-1}\}$ that each module may fail any time and propagate error to any other process. To add redundancy to this system we organize our fault tolerant system as follows.

A. Fault-Free Execution

A new system consists of module sets $M_0=\{m_0^0,m_0^1,...,m_0^{n-1}\}$ and $M_1=\{m_1^0,m_1^1,...,m_1^{n-1}\}$, where $m_i^k\ 0 \le i \le 1, 0 \le k \le n$ is the i-th version of m^k. Message transmission between these two sets of processors is completely isolated, i.e. each module of set M_i receives and sends messages only from and to modules from set M_i. So, a failure in a module in M_0 does not propagate to any module in set M_1 and vice versa. When version m_i^k creates a checkpoint, it compares its checkpoint to the last checkpoint created by version m_{1-i}^k to check their input and output messages with each other. If both versions agree on each other checkpoints, it means that both processes are in a correct state, thus they continue processing. Each received message must be logged by the receiver copy.

B. Fault Discovery Execution

If one or both versions do not agree on each other's checkpoint, it means that one of two processes is in failed state. But it is unknown that which of these two processes has failed, also it is unknown whether the failed process has failed itself or its failure has been propagated from another failed module. To discover this, we use a third processor to start an additional copy of one arbitrary version from the last correct checkpoint that both versions agree on it. Note that while the spare copy is processing, main modules are not blocked and continue processing.

Without loss of generality we start an additional copy from version number 0, called $m_0^{k\prime}$. Now we copy the last correct checkpoint from m_1^k to it, and repeat received message log of m_1^k from last correct checkpoint up to the next checkpoint. After processing these input messages, $m_0^{k\prime}$ creates a checkpoint, and then it compares its checkpoint to checkpoints from two primary processes that they did not agree on their checkpoints. Three cases may occur:

Case 1: $m_0^{k\prime}$ agrees with m_1^k but does not agree with m_0^k. In this case we observe that m_0^k and $m_0^{k\prime}$, two copies of a version that execute exactly the same code, receive their input messages through two different channels (m_0^k from module set M_0 and $m_0^{k\prime}$ from input message log of m_1^k i.e. module set M_0), thus from disagreement between these two copies, we conclude that two input messages are inconsistent. On the other hand, we observe that $m_0^{k\prime}$ and m_1^k, two different versions of a module with different source code, receive exactly the same data, and after execution they agree on their

checkpoint, it means that there is no inconsistency between processes of these two copies. From these two observations we conclude that the failure is propagated from other modules, which is shown at Figure 1.
In this case the protocol does nothing and waits for the other modules to find the self-failed module.

Case 2: $m_0^{k\prime}$ agrees with m_0^k but does not agree with m_1^k. In this case we observe that two version of a module ($m_0^{k\prime}$ and m_1^k) receive same data (input message log from m_1^k from the module set M_1) but the disagreement between them means that they generate different outputs from exactly same input data. Thus we conclude that these processes behave different and one of these two versions is certainly failed itself, and not by faulty messages. On the other hand agreement between $m_0^{k\prime}$ and m_0^k means that the two copies of a version that execute exactly the same source code, but receive their input data from two different channels, agree on their checkpoints and then there is no inconsistency between input messages of the two versions. Both of these observations confirm that the failure is internal, and the other processes are failure-free, so we discover that one of the two versions m_0^k *and* m_1^k is self-failed. This case is shown at Figure 2.

In the next step, we will discover the failed node, while the primary versions are not blocked and still running. In this step, we use another spare node to start a third version of the module m^k called m_2^k. As described, in case 2, we observe that the input data from both module sets are correct, so there is no difference in choosing version to copy its state to the spare version. We copy the last correct state of an arbitrary version to the spare version and then repeat the input message log of that version for it. The module m_2^k after executing its process creates a new checkpoint and then compares it to the last checkpoints created by two primary versions. The correct version, is the version that m_2^k agrees with it. If m_2^k does not agree with any of the two primary versions, it means that more than one of three versions are failed, and TMR approach is unable to find the correct version. This situation forces system to reconfiguration and roll back to the last correct state.

Case 3: $m_0^{k\prime}$ does not agree with any of the two versions m_0^k and m_1^k. This means that more than one process has failed in the current checkpoint interval and this makes recovery process impossible, therefore reconfiguration and rollback is necessary. But there are some conditions that only one failure in a checkpoint interval may result inconsistency in both process and message. Such conditions take place when the failed process sends faulty messages to other processes, and after some steps the failure propagate to itself and make its message log faulty, we call this pattern *propagation loop* which is shown in Figure 3. In this situation, both process and message log inconsistency is detected.

We can detect and solve propagation loop problem by a small change in checkpointing and message passing method: when a module sends a message, it piggybacks the information about the other modules that effect on this message and their checkpoint number. Since only information about recent checkpoints is needed, information about previous checkpoints can be discarded, so it does not have high communication overhead. When a process receives a message that has effected by itself in the current checkpoint interval, it creates an additional checkpoint. After that, it can whether perform the comparison task to completely avoid propagation loop, or postpone it until its predefined checkpoint comparison time. If module compare checkpoints immediately and after that a condition like case 3 occurs, it can certainly decide that more than one failure occurred and rollback to last consistent checkpoint. But if we choose the postpone approach, and a failure like this case occurs, then the module must also check previous forced checkpoints to see whether a case like case 1 or 2 occurs or not, if we reach such states, the fault detection and recovery continues, but if it reach the last consistent checkpoint and did not found such cases, it discovers that more than one failure occurred and rolls back to its last consistent state.

C. Fault Recovery Algorithm

When detection of failed module finished, current states of failed module set must be replaced by failure-free module-set. As noted above, when the failure detection process gets started, other processes does not block and might create new checkpoints, so while fault detection process, if another failure occurs in the failure-free module set, this replacement will replace the failed checkpoints by some other failed checkpoints, the failure will permanently remain in the system. To avoid such cases, it is necessary to replace the faulty checkpoints, by last confirmed checkpoint from the other module set, not the last created checkpoint.

D. Garbage Collection

In order to reduce usage of stable storage capacity, useless message logs and checkpoints must be deleted. When a module finds that the correctness of a checkpoint can be completely confirmed by the other module, It can remove all previous checkpoints and input message logs that are processed before tanking this checkpoint.

V. Performance Analysis

In this section a brief analysis and comparison of level of fault tolerance, execution time and communication overhead our method with the existing roll-forward recovery schemes is made.

A. Level of Fault Tolerance

Responsive roll-forward recovery [6] and postpones all message transmissions until the correctness outgoing message is confirmed by the other replicas. The m^2 [5] approach postpones all message transmissions until correctness of the incoming messages are confirmed by the other replicas. Thus, these schemes will detect and recover faults successfully. The *odd-even* method [5] cannot determine the correctness of receiving messages until the next message receives from

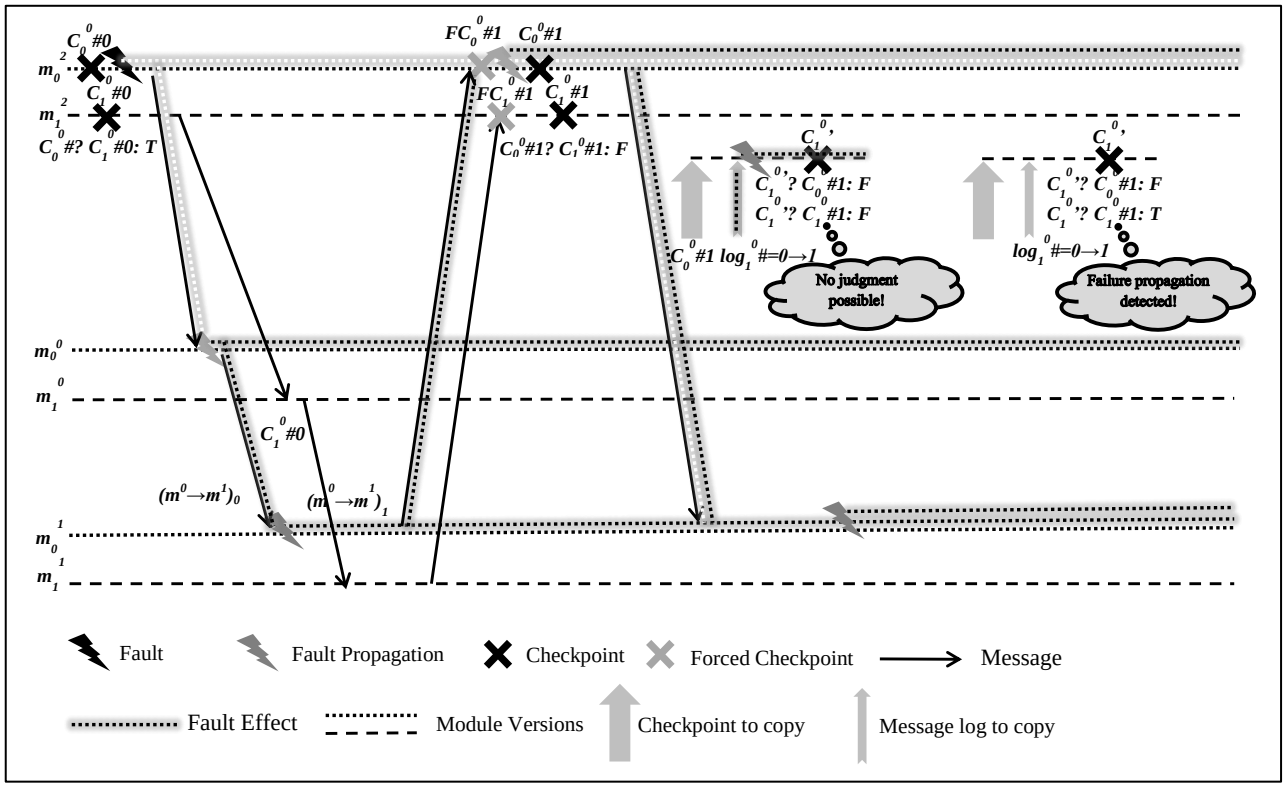

Figure 3-Solve propagation loop

another replica. Sobe in [5] explains that this characteristic is not a weak point because error propagation affects only one of two replicas. But it seems that propagation of error to other modules may make some problem when the spare module starts. Because if the module that is detected to be faulty, does not yet confirms its own input messages, it could not determine that which input message is correct to replay for the spare module? It seems that in the case of high response delays in replicas of a module, odd even approach may be unable to detect the source of failure and recover affected modules. Our scheme because of isolating two set of module versions, in the case of a single failure, has always one fault-free module set, and when a version discovers a disagreement point at any time, it can detect the faulty module and recover all other affected modules.

B. Communication Overhead

In responsive roll-forward recovery [6], every message must first be sent to a voter, and then the voter sends the message to the target modules. This means that for any message in a system without fault tolerance mechanism, three messages in responsive roll-forward recovery must be sent. In m^2 approach [5], each of the copies must send message to the target module in its own set, and also send an additional control message to the relative module in the other module set, i.e. for each message in a system without fault tolerance mechanism, four messages must be sent. In odd-even approach [5], each message are send alternately to the target module in its own module set and the other module set, and in some situations, it uses m^2 steps, i.e. in odd-even approach, for each message in a system without fault tolerance mechanism, sometimes two messages and sometimes four messages must be sent, of course in odd-even protocols m^2 steps rarely occur. In non-blocking roll-forward, because of isolating module sets, each modules send messages only to the target module in its own set, therefore, in our approach, for any message in a system without fault tolerance mechanism, only two messages must be sent. The comparison of communication overhead of these schemes is summarized in Table 1.

Table 1- Comparison of communication overhead of roll-forward methods

Recovery Scheme	m^2	odd-even	Responsive	Non-blocking
No. of messages for *k* messages in a system without fault tolerance mechanism	4*k*	>2*k*	3*k*	2*k*

C. Execution Time

In order to evaluate execution time of our scheme and existing schemes, a simulation is developed and the results shows that non-blocking roll-forward recovery has lower execution times than responsive and m^2 approach. By increasing the mean response time of modules, containing process time and message transmission delay, roll-forward recovery schemes

has better time performance than the other schemes. The results are shown at Figure 4.

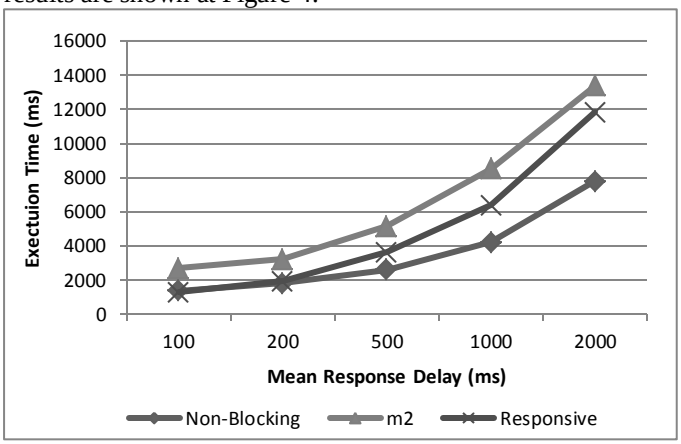

Figure 4 - Execution Time Comparison Results

VI. CONCLUSION

A new recovery scheme for message passing systems called non-blocking roll-forward recovery was presented. This scheme is more appropriate for conditions that the mean and variance of response delays are high. Because in existing blocking methods, execution time for each message in the whole system will be equal to maximum execution time of each module sets. But in non-blocking methods, execution time of each message in a module set is not affected by the other set. The basic assumption of all N-Version Programming and duplex systems that explains a very low probability of failure in more than one of three versions is held. In the case of more than one failure in two versions, rollback recovery and reconfiguration solution is used. The basic assumption of roll-forward systems that explains the very low probability of more than one failure in a checkpoint time interval is held too. On the basis of the said assumption, we can choose the checkpoint interval, with respect to the prediction of failure probability of versions and excepted success rate of roll-forward recovery scheme. In other words, a tradeoff between checkpointing overhead and rollback overhead must be performed.

***Abstract*— N-version programming (NVP) employs masking redundancy: N equivalent modules (called versions) are implemented independently and run concurrently. The results of their execution are adjudicated by a special component that defines the correct majority result and eliminates the results of the versions in which design faults have been triggered. The disadvantage of using these schemes is that they need to block the receiver process until each received message is confirmed by the other version, which results in high time overhead. In the case of variant response latencies, consisting of processing time and message transmission delay, these techniques would not be efficient. In this paper a new non-blocking NVP approach based on capturing the causality between requests and response is proposed. This approach does not need to block the versions to confirm the output. The simulations result show that for acceptable values for probability of failure per demand (pfd) and simultaneous active requests, our approach has lower execution time.**

***Keywords*— Causal Memory, N-Version Programming, Byzantine Fault Tolerance**

I. INTRODUCTION

Distributed systems are widely used for applications with a high demand on computational power and real-time behavior. However the benefit of such systems is accompanied by a higher susceptibility to faults, exponentially increasing with the number of nodes.

Failures can be categorized based on their behavior, in three category crash failures, omission failures and byzantine failures. In the case of crash failures, a faulty process stops executing prematurely, in the case of omission failures, faulty process intermittently omits to send or receive messages, and finally in the case of byzantine failure, faulty process can exhibit any behavior. As an example, a faulty process can change its state arbitrarily, send messages with erroneous content, or send different messages to distinct processes and no message to other when it should send the same message to all[1].

Faults can be categorized by the phase in which they are introduced: Design faults are those which arise during the system design or during modification of system. Operational faults are ones which appear during the system lifetime and are caused due to physical reasons e.g. hardware failures or failure of communication network in the system. Generally, design faults are much harder to tolerate than operational faults.

The root cause of failure of hardware components like nodes and links is frequently physical failure. Software, in contrast, has no physical properties; it is a totally conceptual entity. Hence, physical faults cannot exist in software. Software faults are always design faults. That is, a fault in the software due to incorrect designs or presence of “bugs”, which are usually caused by human errors (in contrast to physical failures, which are caused by natural laws). To build software that can handle faults in its components, we need techniques that can cope with design faults. We will call such software fault tolerant software[2].

A system is fault tolerant if it can mask the presence of faults using redundancy. The goal of fault tolerance is to avoid system failure, even if faults are present.

It is clear that only replicating the same component will not help in coping with design faults, because if software has a design fault, then all replicas of the component will also have the same design fault, and hence the fault cannot be masked. To solve this problem the redundant units are intended to compensate for, or mask a failed software unit when they are not affected by software faults that cause similar errors at cross-check points. Therefore each simplex unit in set of units needs to be built separately and independently of the other members of the set. This is the concept of software design diversity

N-version programming [3] was the first technique developed for employing software diversity to tolerate software faults. N versions of the same (sub-) program are developed diversely from the same specification (there are many ways of achieving diversity here, e.g. the use of different programmers, languages, algorithms, etc. [6]). The versions run in parallel and the results of their execution are adjudicated by a special component which calculates the majority result to be returned as the result of the execution of the diversely implemented program.

Recently several authors have developed object oriented schemes for N-version programming. The units of diversity in these schemes are classes/objects. The idea is to implement several class versions which meet the same specification of the basic class. The authors of [3] call this approach class diversity, as opposed to method diversity which assumes diverse implementation of the same method. In class diversity the implementation of the basic class is built out of several object versions.

II. N-VERSION PROGRAMMING AND DESIGN DIVERSITY

In N-version Programming approach, versions are implemented independently and run concurrently. The results of their execution are adjudicated by a special component that defines the correct majority result and eliminates the results of the versions in which design faults have been triggered. Special care should be taken to decrease the common mode failure among versions; this is why one uses diversity in methodologies (languages, tools, etc.) while developing them. The correct functioning of an N-version program very much depends on how the run time support works, its responsibility is being to run versions in synchronized parallel till their completion, pass the results to the adjudicator, etc. Many schemes based on the general ideas of NVP have been developed since then.

We have recently developed an NVP scheme intended for concurrent object oriented languages which addresses the problems of version control (the synchronization, concurrency and distributedness of the diverse class operation), proposes a clear internal structure of the diversely-implemented (DI) class and discusses interfaces and functionalities of its subcomponents. Another aim of this research is to investigate engineering steps for applying class diversity in standard languages.

In developing this scheme we have followed all above-mentioned principles of structured NVP. Developers of version objects use the same class specification.

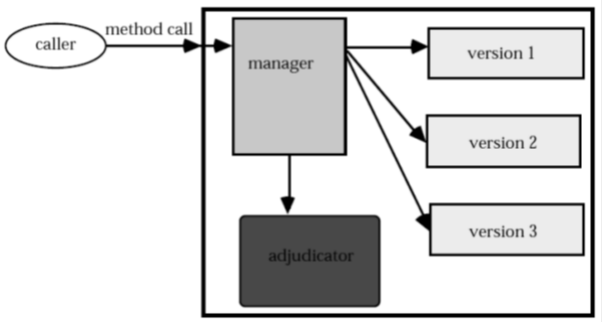

Figure 1- N-Version Programming Architecture

Versions are declared (hidden) inside the DI class. In addition, this class has the adjudicator object and the manager object inside it (see Figure 1). In our scheme we clearly separate their functionalities and describe their interfaces. The manager controls the execution of the scheme: it starts when a method is called, calls versions and the adjudicator object and returns results to the caller. Version programmers do not need to take notice or to know of other versions or the fact that they are parts of NVP. All components inside the DI object are built by inheriting from the provided standard classes and from the application class to be designed diversely. When a method of a DI object is called, the manager calls this method in all N versions in parallel and waits for their results to pass to the adjudicator. The adjudicator compares them and returns the majority results, so that the correct output results can be passed to the caller. If there is no majority, the manager signals a failure exception.

III. PRELIMINARIES

A distributed system is considered as different processes $ap_1, \dots, ap_n$ such that they communicate to each other by message passing through FIFO and reliable channels with finite delay.

Each process ap_i has a memory that contains some variables noted by $\boldsymbol{\mathcal{M}_i} = \{m_1, m_2, \dots, m_l\}$.

The behavior of a process ap_i is considered as a sequence of states $\boldsymbol{\mathcal{S}_i} = \langle S_i^1, \dots, S_i^k \rangle$ such that each state consists of some values for the variables in the memory of the process noted as $S_i^j = \{x_1, \dots, x_l\}$. Each state transformation is written as $S_i^j \xrightarrow{o} S_i^{j'}$. Transformation $\xrightarrow{o}$ means that operation o is done[8].

$$S \xrightarrow{o^1 o^2 \dots o^n} S' \Leftrightarrow S \xrightarrow{o^1} S \dots S \xrightarrow{o^n} S'$$

Possible operations that cause transformation from a state to another are listed below[9].

- *Writing a new value into a variable in the current state of the process*. Operation w_h stands for writing a new value into the variable m_h.
- *Reading value of a variable from the current state of the process*. Operation r_h stands for reading the current value of variable m_h.
- *Sending message to another process.* Operation snd_i stands for sending a message to the process ap_i.
- *Receiving message form another process.* Operation rec_l stands for receiving a message from the process ap_l.
- *Waiting until receiving the next message*. This operation is written as $wait$.

IV. FORMAL DESCREPTION OF CAUSALITY

A. Execution

Behavior of a process can be partitioned into a number of *executions*. A sequence of transformations is named an *execution* if it is in the form of $S \xrightarrow{rec_l o^1 o^2 \dots o^n wait} S'$, mean that it starts with receiving a message and finishes with waiting for receive the next message. The inner operations might be write, read, or send message operations. Thus, an execution can be written in a simpler way by the sequence of operations occurred in it in the form of $E = \langle rec_l, o^1, o^2, \dots, o^n, wait \rangle$. So the behavior of the process ap_i can be written by a sequence of executions in the form of $\boldsymbol{\mathcal{E}_i} = \langle E_i^1, \dots, E_i^k \rangle$.

B. Relations Between Operations

1) Happened Before Dependency

Lamport in [10] presents the concept of the happened-before relation. The happened-before relation $\prec_i^{hb}$ is a partial ordering such that $o \prec_i^{hb} o'$ if and only if the operation o in ap_i is done before the operation o' in ap_i.

2) Causal Dependency

The causality relation $\prec_i^{ca}$ is an ordering for two operations o and o' in a process ap_i, $o \prec_i^{ca} o'$ if and only if one of this conditions are held.

1. Both o and o' belong to the same execution and $o \prec_i^{hb} o'$.
2. o is a write operation on the variable x and o' is a read operation from x that executed after o (also named as read-from relation).
3. There is some o'' such that $o'' \prec_i^{ca} o'$ and $o \prec_i^{ca} o''$.

C. Relations Between messages

For two execution $E_i^k = \langle rec_l, o^1, o^2, \dots, o^n, wait \rangle$ and $E_i^{k\prime} = \langle rec_{l\prime}, o^1, o^2, \dots, o^{n\prime}, wait \rangle$ from the process ap_i, the causal output-input dependency relation $\prec_i^{oica}$ is defined as followed:

$$\forall snd_j \in E_i^{k'}, : rec_l \prec_i^{oica} snd_j \Leftrightarrow$$
$$(rec_l \prec_i^{hb} rec_{l'}) \wedge (\exists m_h \in \mathcal{M}_i | r_h \in E_i^k \wedge w_h \in E_i^{k'}) \wedge$$
$$((\exists rec_{l''} \in E_i^{k''} | w_h \in E_i^{k''})$$
$$\Leftrightarrow rec_{l''} = rec_{l'} \vee rec_{l''} \prec_i^{hb} rec_{l'})$$

In simpler words, a sent message of a process is depended to a received message of another process, if it read a value from a variable that another process wrote it before.

V. Non-Blocking N-Version Programming

In this section, a new approach for controlling the correctness of versions' outputs is proposed. In this approach, the versions are divided into two isolated groups that send and receive message only from versions in their own group. The versions record checkpoints of their state periodically and after each execution, send their output messages directly to the adjudicator of the target process. They also send a hash code of the received message and its checkpoint number to the adjudicator process. The adjudicator captures the timestamp of received messages and forwards them to the target versions. It also checks the compatibility of the outputs of the versions periodically. If it discovers inconsistency, it finds the faulty version by running a third version. The details of the failure discovery and recovery are explained below.

A. Process Dependency Graph

The process dependency graph for process ap is defined as a bipartite graph $G = (V, U, E)$ such that R_{ap} is the set of the messages that has been received by ap and R_{ap} is the set of messages that have been sent by R_{ap}.

$$V \in R_{ap}, U \in S_{ap} \text{ and } E = \{(v,u) | v \in V \wedge u \in U \wedge v \prec_i^{oica} u\}$$

Suppose that p and p' were two versions of a process that has been developed using N Version programming techniques and performing identical processes on their input data. If both of these versions are processing correctly and they have implemented techniques for preventing state divergence, their process dependency graph must be identical at the end of processing. So if at the end of processing, there was any difference between the process dependency graph of these two versions, we conclude that these execution are not identical and consequently we discover that one of two versions are faulty.

B. Fault Discovery and Recovery

When two versions are processing the same input at the same time, capturing input and output messages with timestamps and their causal dependencies makes it possible to discover inconsistency between versions caused by faults. Such that if one of two versions generates an output from some input messages that have causality dependency with them, and also the side version already has received all those input messages, but after a specified timeout does not generate the same output, we can conclude that one of two versions are faulty. The timeout value is equal to maximum expected delay for processing the message and communication delay. At this time, the last checkpoint of one of one the two versions and the message log after the last checkpoint (in log-based recovery approach is used) is send to a third version and the output of the third version is compared with two other versions. Thus the faulty version becomes discovered. Then the last checkpoint of the faulty version that seems to be error-free is sent to the third version and the faulty version is replaced by the third version.

VI. Performance Evaluation

A simulation is developed using SimJava 2 Tool [11] and the execution time of a replicated distributed program using primary-backup and causal memory techniques are compared. There are 6 pairs of nodes that communicate via message passing, each pair of processes are developed using N-Version Programming approach and perform identical executions on the same input. The process and communication delays are generated using exponential distribution with mean value 200 SimJava time units for communication delays and 50 SimJava time units for delay of processing each input message. Each test is started by a number of initial requests (3, 6, 12, 30 and 60), and each request is assumed to be processed by 500 steps in different processes, and after each step, the request is sent to another process to continue execution. The tests are performed in different conditions on the active requests and the probability of failure per 10000 messages (0,1,2,5,10,15,20,30,50,100). The results show that the non-blocking approach is appropriate for the systems with low probability of failures and low traffic of requests. If the probability of failure becomes larger than a specific threshold, the execution time of the non-blocking method rapidly grows. This threshold is lower for higher active requests.

As shown in figure 2, this threshold for 3 active requests is about 100 faults per 10000 input messages, and for larger fault probabilities, the responsive method has lower execution times. For 15 active requests, this threshold is about 50 faults per 10000 input messages (figure 3) and for 30 active requests; this value reduces down to 10 faults per 10000 input messages (figure 4). These results are acceptable because in most of important applications the expected values for probability of failure per demand (pfd) are assumed about 10^{-4} to 10^{-3}. Therefore, for such values of pfd, our approach has lower execution times.

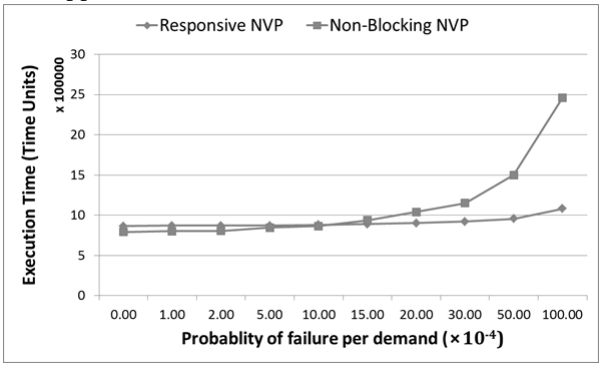

Figure 2 – Execution Time for 30 Active Simultaneous Requests

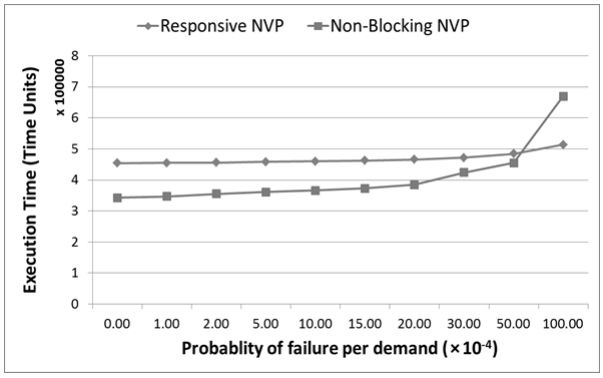

Figure 3 – Execution Time for 6 Active Simultaneous Requests

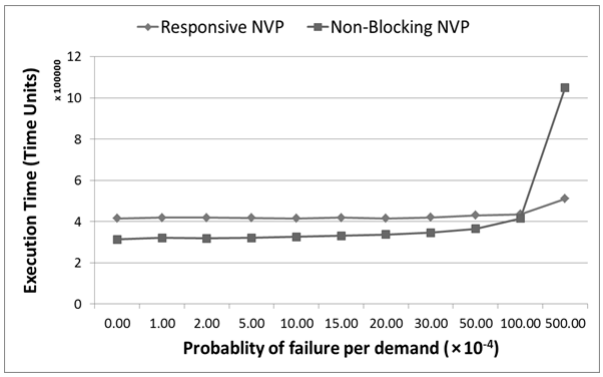

Figure 4 – Execution Time for 3 Active Simultaneous Requests

VII. CONCLUSION AND FUTURE WORK

A new recovery scheme for message passing systems called non-blocking N-Version Programming was presented. This method reduces blocking processes that was used to confirm the correctness of each output message. The simulation has shown that the performance of this method for higher probability of fault and higher active requests are lower than the responsive method because large increase in execution time is possible. It is necessary to propose and develop hybrid methods using responsive and non-blocking approaches to develop partially blocking methods to avoid divergence of state between two versions, and adopt the methods with the environmental variables such as active requests and probability of fault.

Abstract— **Presented in this paper is a cellular automata based algorithm for computing voronoi diagram of arbitrary shapes. There is no limitation for sites; they can be circles, rectangles, points or anything else. Our algorithm outperforms previous works in speed and accuracy. The proposed algorithm constructs the correct voronoi diagram as a wave from each site is propagated to the environment. When waves collide to each others, the borders of voronoi cells are built.**

We used asynchronous CA that made our algorithm faster. Our algorithm can be used in distributed systems and supposed as a parallel strategy to build voronoi diagram of arbitrary shapes.

I. INTRODUCTION

Computational geometry is involved with the design and analysis of algorithms for geometrical problems. In addition, other more practically oriented, issues of computer science such as computer-aided design computer graphics, robotics, pattern recognition, and operations research give rise to problems that intrinsically are geometrical. This is one reason computational geometry has attracted numerous researches in the past decades and is a well-established area today. For established sources, we refer to the survey by Lee and Preparata [1] and to the textbooks by de Berg [3] and Preparata and Shames [2].

Readers familiar with issues of computational geometry have noticed, an increasing interest in a geometrical structure called the Voronoi diagram. This tendency can also be observed in combinatorial geometry and in a considerable number of articles in computer science journals.

Voronoi diagram is one of the most fundamental data structures in computational geometry. It has applications in wide area of disciplines.

In the simplest case, let *S* be a set of points in Euclidean space. For almost every point *x* in the Euclidean space, there is one point of *S* closest to *x*. The word "almost" is used to indicate exceptions where a point *x* may be equally far from two or more points of *S*. If *S* contains only two points, *p* and *q*, then the set of all points equidistant from *p* and *q* is a line. That line is the boundary between the set of all points closer to *p* than to *q*, and the set of all points closer to *q* than to *p* and is the perpendicular bisector of the line segment from *p* to *q*.

In general, if S is a set of d-dimensional points, the set of all points closer to a point *c* of *S* than to any other point of *S* is the interior of a (in some cases unbounded) convex polytope called the Dirichlet domain or Voronoi cell for *c*. The set of such polytopes tessellates the whole space, and is the voronoi tessellation corresponding to the set *S*. If the dimension of the space is only 2, then it is easy to draw pictures of voronoi tessellations, and in that case they are called voronoi diagrams.

Voronoi cells can be defined for metrics other than Euclidean (such as the Manhattan[4] or Karlsruhe [5],[6]) distances. However in these cases, the Voronoi tessellation is not guaranteed to exist, since the equidistant locus for two points may fail to be subspace of codimension 1, even in the 2-dimensional case.

Voronoi cells can also be defined by measuring distances to objects that are not points, for example in [7] the authors present a sweepline algorithm to compute the Voronoi diagram of a set of circles in a two-dimensional Euclidean space. The radii of the circles are non-negative and not necessarily equal. It is allowed that circles intersect each other, and a circle may contain others. The proposed algorithm computes the correct Voronoi diagram as a sweepline moves from top to bottom. While moving on the plane, the sweepline stops only at certain event points, where the topology changes occur for the Voronoi diagram being constructed.

A weighted Voronoi diagram[8] is the one in which the function of a pair of points to define a Voronoi cell is a distance function modified by additive or multiplicative weights assigned to sites.

Voronoi diagrams can be generalized in many ways [9, 10]. One generalization is to point sets in higher-dimensional spaces. In E^d, the maximum combinatorial complexity of the Voronoi diagram of a set of *n* point sites (the maximum number of vertices, edges, and so on, of the diagram) is $\Theta(n^{\lceil d/2 \rceil})$ [11] and it can be computed in $O(n\log n+n^{\lceil d/2 \rceil})$ optimal time [12], [13], [14].

The Voronoi diagram of *n* points in *d*-dimensional space requires $O(n^{\lceil d/2 \rceil})$ storage space. Therefore, Voronoi diagrams are often not feasible for $d > 2$. An alternative is to use approximate Voronoi diagrams, where the Voronoi cells are approximated by a fuzzy boundary.

In this paper we generalize Voronoi diagrams such that the sites can be any shape in the plane. We focus on 2D space but the algorithm can be used for 3D space too. Presented in this paper is a cellular automata based algorithm for voronoi diagram of sites with any shape. There are some previous works[28][29] that construct voronoi diagram by cellular automata, but they are not as fast as the algoriitm presented in this paper because in each cycle we don`t process all cells. In addition the waves for sites are propagated in circle which makes our algorithm

more accurate than others. For example in [28] waves are propagated in rectangle.

The proposed algorithm constructs the correct Voronoi diagram as a wave from each site is propagated to the environment.

The paper is structured as follows: Sections II and III provide a review of cellular automata, section IV defines the problem tackled in this paper, in section V our algorithm is proposed and in section VI, we analyze the algorithm.

II. Cellular Automata

From the days of Von Neumann and Ulam who first introduced the concept of cellular automata (CA), to the book of Wolfram "A New Kind of Science" [15], the simple structure of CA has attracted interests of researchers from various fields. It has been subjected to rigorous mathematical and physical analysis for the last fifty years, and its application has been shown in different branches of science. Enormous research papers are published every year. Specialized conferences and special issues of various journals on CA have been initiated in the last decades. Several universities around the world have also started offering courses on cellular automata. Furthermore, as many as seven hundred books are found to exist on cellular automata when we visit the web-site www.amazon.com. The reason behind the popularity of cellular automata can be traced to its simplicity, and to the enormous potential it holds in modeling complicated systems, in spite of their simplicity.

A cellular automata in fact is a simple model of a spatially extended decentralized system made up of a number of individual cells. The communication between cells is limited to local interaction. Each individual cell is in a specific state which changes over time depending on the states of its local neighbors. The overall structure can be modeled as a parallel processing device. However, after several iterations, this simple structure produces complex patterns displaying the potential to simulate different sophisticated natural phenomena.

The concept of CA was initiated in the early 1950's by J. Von Neumann and Stan Ulam [16]. VonNeumann showed that a cellular automata can be universal. He proposed a CA, each cell of which has a state space of 29 states, and showed that the devised CA can execute any computable operation. However, due to its complexity, Von Neumann rules were never implemented on a computer. On one hand, it was proved that a decentralized machine(CA) can be designed to simulate any arbitrary function. On the other hand, the machine becomes as complex as the function it tries to simulate. This very theoretical dichotomy has since driven research on CA [17], [18], [19], [20].

Based on the concept of universality, scientists have tried to develop simpler and more practical architectures of CA which can be used to model different type of applications. In this respect, two notable developments can be credited to Conway and Wolfram. In the 1970, the mathematician John Conway proposed his now famous game of life [21], which received widespread interest among researchers. In the beginning of the eighties, Stephen Wolfram has studied in much detail a family of simple one-dimensional cellular automata rules (now famous Wolfram rules [22]), and showed that even these simplest rules are capable of simulating complex behavior.

The next section presents a survey of different types of cellular automata structures proposed over the years. More information about cellular automata is found in [27].

III. Neighborhoods

A cellular automata in fact is composed from a set of cells, which is called the space of the cellular automata. Each cell has the same number of neighbors around itself and is equipped with a copy of the same automata whose alphabets make the set of states of the cellular automata. The transition table of this automata defines what we call the local transition function of the cellular automata. Current state of the cell is identified by the configuration of neighbors of the cell. The local transition function by the use of current state of each cell introduces the next related state. We have a clock defining a discrete time starting from the initial time usually set to zero. At each cycle the new state of cells is introduced by the transition function. What we have just described is a deterministic cellular automata as for each neighborhood; the local transition function defines a single new state.

The space of the automata is important. Traditionally, space is a line of cells and each cell is identified by an integer which is its coordinate (Fig. 1.). In The Euclidean plane, identified with Z^2, the neighborhoods of a cell can be defined in very different ways. For a line there are two of the neighbors which are at the left and at the right of a cell, which is called the symmetric neighborhood of radius 1. This means that for a cell identified by integer x, we shall later say cell x, the neighbors are cells x-1 and x+1.

In the Euclidean plane, there are traditionally two kinds of neighborhoods. If the coordinate of a cell is (x, y), its von Neumann neighbors consists of cells (x, y), (x, y+1), (x−1, y), (x, y−1) and (x+1, y). This neighborhood is illustrated by the left hand side of the Fig. 2. Another neighborhood which is also much used is Moore neighborhood which its neighbors are illustrated in the right-hand side of the Fig. 2 Moore neighborhoods of (x, y) also contains the cells (x−1, y+1), (x−1, y−1), (x+1, y−1) and (x+1, y+1).

For the neighbors of a cell (x, y) in von-Neumann there is an alternative too: (x, y+1) is the northern neighbor, (x−1, y) is the western one, (x, y−1) is the southern one, and (x+1, y) is the eastern one. These names allow us to not mention the coordinates and we shall use them. We shall also say that the cell (x, y) sees (x, y+1) through its northern side, (x−1, y) through its western side, (x, y−1) through its southern side and (x+1, y) through its eastern side. Note that these notions are the same as those of 4- and 8-connectedness. More precisely, 4-connectedness Corresponds to von Neumann neighborhood and 8-connectedness corresponds to Moore neighborhood.

The transition function takes the state of the neighbors of a cell, and then defines a state for the current configuration of neighbors. Such a list of states is called a rule. Accordingly, the local transition function can also be represented as a table of rules. We shall adopt this point of view in the rest of the paper. A last but not least, notion has to be introduced, the notion of configuration which is essential in cellular automata. Formally, it is an application of the space into the set of states of the automata. If we apply the local transition function, we define a new configuration. Going from one configuration to a new one by applying the rules, we define a new function, this time

from the set of configurations into itself, which is called the global function of the cellular automata.

However, we shall not look at the succession of the configurations in this way, which is the way mathematicians look at them. We shall devise them one by one, which is a different point of view. In next section,we introduce the problem.

IV. PROBLEM DEFINITION

Denote the Euclidean distance between two points *p* and *q* by dist (*p*,*q*) which is given by:

$$dist(p,q) = \sqrt{(p_x - q_x)^2 + (p_y - q_y)^2} \qquad (1)$$

Let $S = \{s_1, s_2, \ldots, s_n\}$ be a set of n distinct shapes in the plane, which are called sites. For a site s and an arbitrary point z in the plane, let $d_s(z)$ be the shortest euclidean distance between z and a point $p \in S$. Then, we assign z to the Voronoi region of a site s if, and only if, $d_s(z)$ is minimum among all $d_t(z), \forall t \in S - \{s\}$. In other words We define the Voronoi diagram of S as the subdivision of the plane into ***n*** cells, one for each site in *S*, with the property that a point *z* lies in the region of a cell of site *s* if and only if $d_s(z) < d_t(z)$ for each $t \in$ S-{s}.

V. ANYSHAPE ALGORITHM

Our algorithm is able to compute the voronoi diagram when the sites are arbitrary shapes. The sites can be points, circles, rectangles or any other shapes such as the ones presented in Fig. 3.

Our method is similar to the Dijkstra method. We consider the grid structure, i.e., the graph in which the vertices are cells and the edges connect each cell with its eight neighbors.

In ANYSHAPE algorithm, cells are classified into four groups: *known*, *border*, *unknown* and *frontier* cells. The *known* ones are cells for which their site is identified. You should notice that for a *Known* cell, assigned site is the closet one among the others. The *frontier* cells are ones that are not yet *known*, but are the neighbors of the *known* cells. The *border* cells are ones that are equidistance from more than one cell, which means they have some *Known* Neighbors. The *unknown* cells are all the other cells.

In each cycle we don`t process all of the cells, and just process frontier cells; by this approach we increase the performance.

In the first step we, set the state of the cells related to each site as *known*, and then set all valid neighbors to *frontier*. We explain which neighbors are valid later. When a cell is assumed as *frontier*, it is inserted into a Queue, and in other

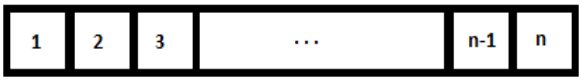

Figure 1. A cellular automata with a linear space

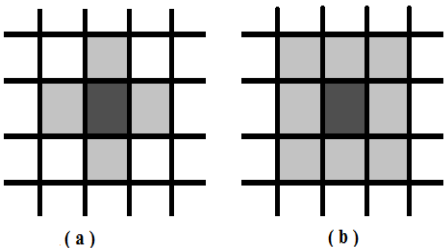

Figure 2. Von Neumann (a) and Moore definition (b) of neighborhoodness.

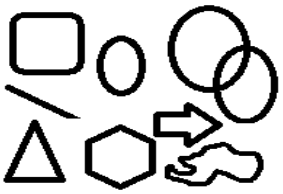

Figure 3. Examples of shapes which can be used as a site.

steps removed and processed. Therefore all of the cells are not processed in each step.

When a cell *c* is removed, we check the neighbors, if there is one cell as *known*, then c will be considered as a *known* one and assigned to a specified site. But if at least two of the neighbors are *known* belonging to more than one site, then cell c will be considered as a *border* one. Notice that when a cell is considered as *known*, then its *unknown* neighbors will be inserted into Queue as a *frontier* one.

So in first step we set site cells to *known*, and propagate a wave to find cells belonging to each site, but there is a problem. In Fig. 4.a , in first step, one cell is considered as *known* and all neighbors as *frontier*, in step 2, all neighbors are assumed as *known* and all neighbors of new *known* cells are considered as *frontier*. Since we are about to compute voronoi diagram in euclidean metric, so wave from each site must be propagated as a circle (Fig. 4.b). Notice that one *unknown* cell *c* belongs to a site s iff wave propagated from s reaches *c* sooner than other waves. But if waves are homogeneously propagated, then this property is not satisfied.

Now, we change the propagation behavior such that each wave is propagated heterogeneously. For a *frontier* cell *c*, we check its neighbors, suppose that just one of the neighbors (e.g. *n*) is *known* and assign it to a site *s*. Now we must set *c* to *known*, but before changing the state we, check weather site *s* is valid for the cell *c* or not.

We define $d_c(c1, c2)$, the distance between two cells. $d_c(c1, c2)$ is the euclidean distance between the centers of c1 and c2. If cell c1 is *known* and assigned for site s, for its *frontier* neighbor c2, we set c2 as *known* in the next step iff (2) is satisfied. In (2), step is the number of cycles and precision is the length of cells` edge. We say c2 is *accessed* by site s, if (2) is satisfied for at least one cell si assigned to S.

$$d_c(si, c2) \leq (step + 1) * precision \qquad (2)$$

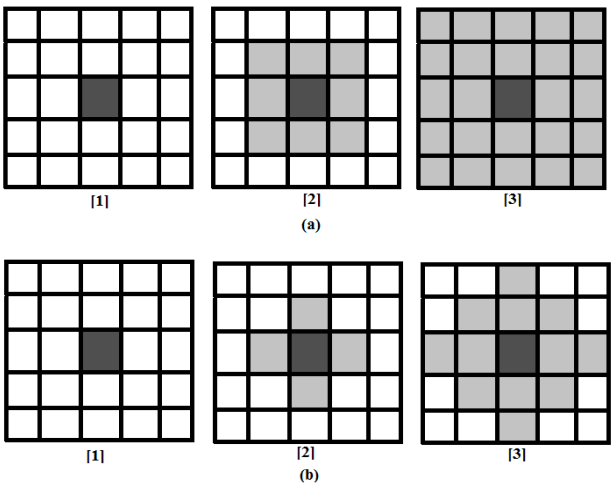

Figure 4. (a).Homogeneous propagation (b). Heterogeneous propagation.

Fig. 5 presents the steps of computing voronoi diagram of a set of points. It is obvious that waves are propagated as a circle. When circles collide to each others, the borders of voronoi cells are built and the wave doesn`t propagate any more.

In this paper, we assume the *precision* as the size of each cell, whatever a cell is smaller our voronoi diagram will be more accurate. In fact by ANYSHAPE algorithm we compute an approximate voronoi diagram.

Fig. 6. presents ANYSHAPE algorithm. In line 1, cells related to each site are assumed as *known* and others as *unknown*. In line 2 a dummy cell is inserted into Q, so each time we find it at the top of the Q, it will be a sign that one cycle is ended. We need to calculate the number of cycles in order to test (2), in lines 8 and 10. When we say cell c1 is accessed by one *known* cell c2, it means c1 is accessible by s.

In line 3, we set the neighbors of site cells in to *frontier* and insert them in Q. You should notice that before insertion we test (2), so in next cycle, when one cell is removed as *frontier* we can be sure that it is accessible and (2) is satisfied for at least one of the neighbors. In line 5, we check cells in Q, until it becomes empty. In line 6, we remove one cell and check its state. In line 8, for a *frontier* cell, if there is more than one site accessing the cell, then it is considered as *border* and if it is accessed by exactly one site, then it is assumed as *known*, and labeled with that site. If one *frontier* cell is changed to a *known* one, then its *unknown* neighbors which satisfy (2) are set to *frontier*, and inserted to Q (line 12).

If the cell's state removed from Q is *known* or *border*, we do nothing and go to line 5. Finally if the cell`s state removed from Q is dummy, then we increment Cycle by one. We continue in this manner until Q becomes empty.

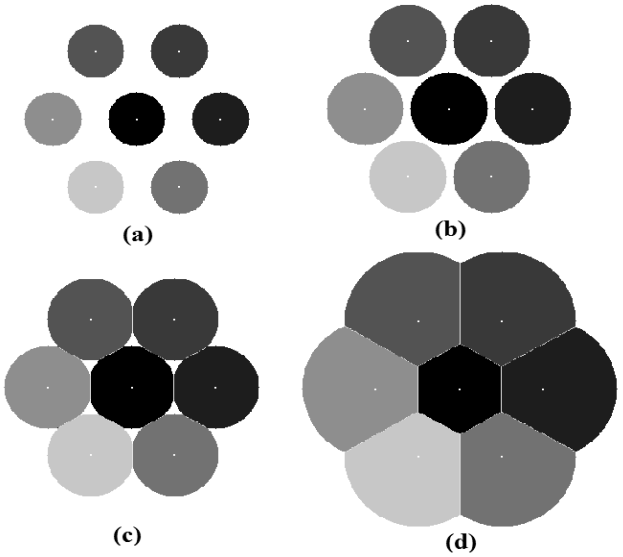

Figure 5. Voronoi diagram for a set of points.

sites, since sites are not points, so waves are not propagated in circles, but it computes the correct voronoi diagram.

VI. ANALYSIS

In this section we first prove the correctness of the algorithm and then present the complexity of ANYSHAPE.

lemma 1. At the end of each cycle l, wave propagated from each site s, covers all of the cells whose distance is smaller or equal to $(l + 1) * \text{precision}$ unless it is accessed by other sites.

Algorithm ANYSHAPE (Data grid g, list of sites s1,…,sn)

1. for k=1,2,…n set the state of cells related to s_1,…s_n to Known , label them with specified site and set all other cells to UnKnown.
2. Insert a dummy cell into Q *// when this dummy cell is at the top of the Queue, it means one cycle is ended.*
3. For neighbors of cells c_1, …,c_n if they are accessible according to (2), set the state of their neighbors as frontier and push them into Queue Q.
4. Cycle = 0
5. While Q is not empty
6. Remove top entry c
7. if c.state = = frontier
8. if c is accessible by more than one known neighbor
9. set c.state to boundary.
10. else if c has exactly one known cell as neighbor
11. Set c.state to known and label it with appropriate site
12. For neighbors of c which their state is unknown, satisfying (2), set the state to frontier and insert them to Q.
13. else if c.state = = known || c.state = = boundry
14. Goto line 5 // do no thing
15. else if c.state = = dummy
16. Insert c into Q // so when this dummy cell is at the top of Queue again it means that one cycles is ended.
17. Cycle = Cycle + 1 *// we update cycle in order to test (2)*
18. EndWhile
19. End Algorithm ANYSHAPE

Figure 6. ANYSHAPE algorithm.

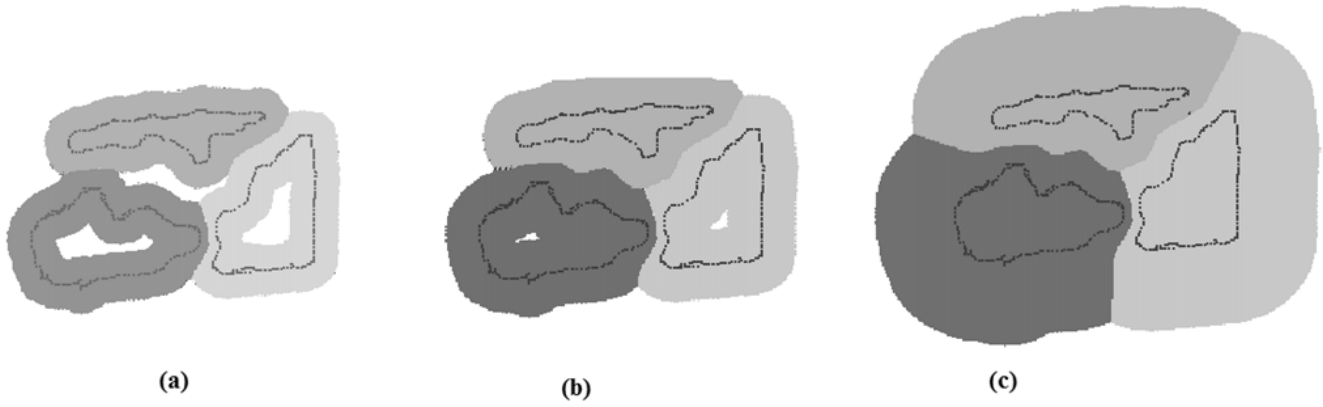

Figure 7. Voronoi diagram for three curved lines as sites

proof. In cycle l, each site is assumed as known and its neighbors which satisfy (2) are inserted into Queue as frontier; so in cycle 2, all of the neighbors satisfying (2) are removed from Queue as frontier and set to known. Generally in cycle n, all of the sites satisfying (2) for cycle n+1 are assumed as frontier and inserted into Queue. Therefore, in each cycle, cells satisfying (2) are removed as frontier, and checked to be as known or border.

lemma 2. In ANYSHAPE algorithm, each cell c is assigned to nearest site s.

Proof. Suppose that ANYSHAPE assigns cell c' to site s' while $d_c(si, c') < d_c(si', c')$where $si \in s, si' \in s'$ and $s \neq s'$. We know that waves from s and s' started at the same cycle. Since c is assigned to s' it means wave propagated from s' reached c sooner than s. we suppose that wave from s reaches c in cycle l while wave from s' covers it in cycle $l' < l$. Assume without loss of generality that $l = l' + 1$. Since s' reaches c in cycle l' and s' in cycle l'+1 so:

I. $(l') * \text{precision} < d_c(s', c') \leq (l' + 1) * \text{precision}$
II. $(l' + 1) * \text{precision} < d_c(s, c') \leq (l' + 2) * \text{precision}$

I and II together indicate that $d_c(s', c') < d_c(s, c')$ which contradicts our first assumption.

By lemma1, we are sure that each wave of one site covers whole cells unless they are accessed by other ones and by lemma2 we can say ANYSHAPE computes the correct voronoi diagram.

Now we analyze the number of cells processed in ANYSHAPE. Suppose that there are n cells. It is clear that when one cell is inserted into queue as a *frontier* one, it will be set to *border* or *known*, that means it will not be processed any more. In each cycle we don`t process whole cells and just process the *frontier* ones. Since each cell has just eight neighbors, so we can claim that, for n cells, ANYSHAPE algorithm processes O(n) cells which is optimal.

VII. Experimental results

Our experimental results were carried out on a 2 GHz processor with 1024 MB RAM on Windows XP professional platform. We used C++ for implementation.

Fig. 8 there is one circle and one triangle as site. The size of the plane is 400× 400 and each pixel is supposed as a cell. As shown in Fig. 8 space is divided into 2 subspaces. One subspace is for the circle and the other one is related to the triangle.

In Fig. 9. There are six circles. In [7] a sweep line algorithm is presented for computing euclidean voronoi diagram of circles. In Fig. 9.b the voronoi diagram computed by [7] is presented and in Fig. 9.a the voronoi diagram computed by our algorithm is illustrated. Obviously our algorithm computes the correct voronoi diagram like algorithm in [7]. In addition ANYSHAPE can compute voronoi diagram for more complex shapes too. In Fig. 10. The voronoi diagram for a set of circles and points is presented.

VIII. Conclusion

The aim of this paper was to construct voronoi diagram of arbitrary shapes. There is no assumption for sites; they can be circles, rectangles or any shape that can be drawn on the paper. We used cellular automata for our model. The accuracy of the constructed voronoi diagram is related to the size of cells. We used asynchronous cellular automata that made our algorithm faster.

Experimental results prove the efficiency and accuracy of our algorithm. In addition, by lemma2 we proved that our algorithm builds correct voronoi diagrams.

Parallel Implementation of a Combustion Chamber Simulation With MPI-OpenMP Hybrid Techniques

L. Környei
Department of Mathematics and Computer Science, Széchenyi University, Győr, Hungary
leslie@sze.hu

Abstract – The parallelization techniques utilized in a study of gas flow in a combustion chamber are described and discussed in this paper. Models of compressible fluid dynamics are solved with the finite volume method, and an additional algorithm, called "snapper" that handles piston and valve movement. In order to achieve an acceptable scaling on a CPU cluster with 240 cores, a two-stage parallelization with MPI in conjecture with OpenMP is implemented.

For some types of physical investigations, the actual spatial region of interest is somehow changing, deforming, or moving in time in a predefined fashion. Handling gas dynamics with piston motion, even with the simplest models requires precaution. Apart from numerical and physical corrections, there are challenges, where multiple types of unstructured, and specially generated deforming grids are handled in a computer system with distributed memory. In the present work the results of the first implementations and benchmarks are presented, which prove to be well scaling for this modest-sized cluster.

I. INTRODUCTION

Fluid dynamics is a basic, widely studied field of physics [1]. The broad industrial application induced its research on computer aided solutions of its models [2]. The past decades' immerse development made high performance computing available to an even wider range of researchers. This turned parallelization of basic CFD problems to schoolbook exercises.

Introducing large enough time dependent deformations to the system will cause difficulties. There are several commercial and open source solutions for CFD problems, like Fluent [3], KIVA [4], or OpenFOAM [5]. However, there are only a few works on highly parallelized solutions for CFD problems with moving boundaries in an arbitrary geometry. My goal is to find an appropriate way to handle solid object movement within gaseous material. This includes finding an algorithm, which is implementable in a high performance computing environment. The first step is the simulation of a four-stroke engine with moving piston and two valves on a cluster architecture system with 240 CPU cores presented here.

Within the simulation the multi component Euler equations are solved in the case of ideal gases [6]:

$$\begin{aligned} \partial_t \rho_k &+ \nabla(\rho_k v) &&= 0, \\ \partial_t (\rho v) &+ \nabla(v \times \rho v + p) &&= 0, \\ \partial_t e &+ \nabla(v(e+p)) &&= 0; \\ p &= \rho(\gamma - 1)e. \end{aligned} \qquad (1)$$

Here ρ and ρ_k are density and partial density respectively, ρv is the impulse density, p is pressure and e is the total energy density. The last equation describes the equation of state for ideal gases with γ being the adiabatic index. No fuel burn or chemical reaction is modeled.

On physical boundaries, i.e. cylinder wall, no-flux conditions apply. For the four-stroke engine simulation intake and exhaust port connections are both to handle both inflow and outflow. Room temperature and pressure are set as initial condition in equilibrium, so gas flow will be induced by piston movement, which will start from the top dead center. Three gas components are used. The first component is let in from the intake port, the residue above the intake valve. The rest of the gas is considered used, and is set as component 3.

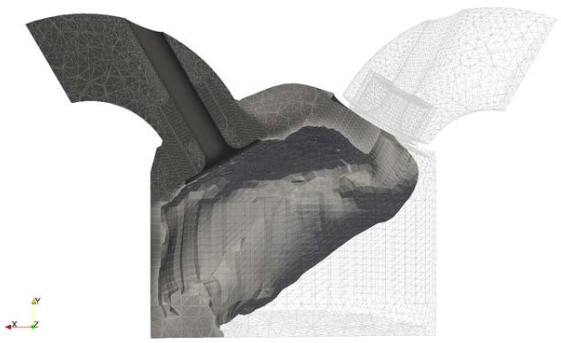

Figure 1. The fresh gas inflow is shown while the intake phase takes place, where darker tones represent higher partial density. The chamber is cut half along the symmetry plane for visualization. The connection mesh on the outlet valve is inactivated on purpose, thus not shown here.

This work is within the frame of the TAMOP-4.2.2-08/1-2008-0021 project called Simulation and optimization is accomplished with the support of the European Union at the Széchenyi István University with a newly created international research team.

Equation (1) is solved using a first order, explicit finite volume method with adaptive time stepping [7]. For the numerical flux function I employ Vijayasundaram's flux splitting method [8]. Boundary conditions and inter-mesh communication is handled by ghost cells [9]. The serial implementation is mostly based on A. Horváth and Z. Horváth's work on moving boundaries [10]. Parts of the flux implementation are based on M. Liebman's work on the GPU cluster acceleration of static-mesh Euler equations [11].

II. IMPLEMENTATION

In this paper the handling of the moving boundary, the valve control, the domain decomposition, data synchronization and hybrid implementation is handeled. Other tasks, which have smaller order CPU time cost, like mesh vertex fitting or interpolation matrix calculation are discussed in another paper [12].

Implementation is done in the C++ language. It uses the research group's framework, PARMOD, which is developed by G. Takács [13]. It also uses certain parts of the BOOST C++ library, mostly for higher level programming and measurements [14]. The BOOST MPI library is not used.

A. Moving Boundary Handling

There are several papers discussing the methods for piston movement with additional neighboring regions present, like the multi-component method [16], the overlapping mesh method [17]. This implementation uses the method called "snapper" [18]. For other stategies, there is an extensive review done by M. Wierse, who also introduces a cutting method, where cells are cut by the piston plane [15].

Using the "snapper", if the deformation of the mesh is small, cells among the moving surface are distorted. This leaves mesh topology intact. As the cells get too flat or too elongated, they are merged or split to regular size cells (see Figure 2).

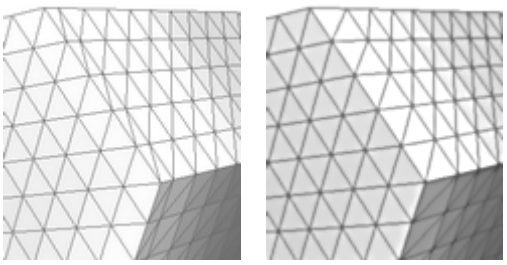

Figure 2. The "snapping" is the interpolation of the last two layers of data (left) to one layer (right). This is also done backwards, if the area is moving the opposite way.

For stationary cell surface flux calculations are unaffected. For inner surfaces, and inter-mesh surfaces within the gas space the eigenvalues of the flux function matrices are to be adjusted. On a physical mesh boundary additional special boundary conditions apply to obey conservation laws [10].

The main advantage of this technique is that snapping is done rarely, as slight distortion does not change the mesh topology. Also the time cost of the snapping is proportional to the area of the moving surface; this gets less decisive for higher density meshes. The algorythm does require heavy bookkeeping on the other hand, particularly where meshes are split into multiple domains.

B. Valve Discretization

The mesh geometry data of the combustion chamber presented here is mostly handiwork. To model their movement, valves must be enclosed into specially generated, structured, deformable meshes.

To achieve this, the valve surface is drawn with meshing software first, then an additional unstructured mesh is generated, to flat out the valve's curvy "neck". Using the surfaces, the shift and the skew of the valve, four structured meshes are also generated to mimic actual valve movement. Finally the piston crown, intake and exhaust ports are adjusted to the valve structure.

The finished form of the mesh structure is shown on figure 3. Piston motion is modeled by the darker shaded structured mesh at the bottom. An additional translating unstructured mesh is attached below, which serves to adapt the uneven piston surface.

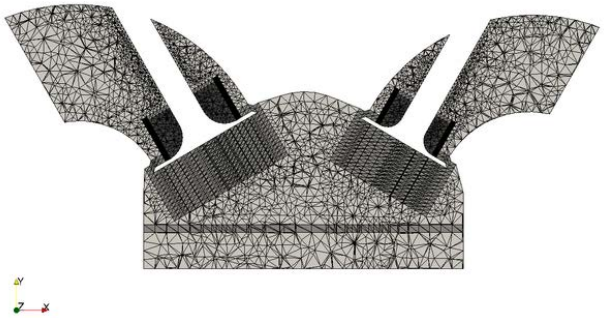

Figure 3. The mesh composition of the 2-valve and piston system is shown in the top dead center (TDC) position. Lighter-shaded parts show unstructured, non-deformable meshes, while darker-shaded parts show structured, deformable ones.

There are five meshes for each valve, supporting its movement. The generated structured mesh is flatting out the curvy "neck" of the valve. A structured, deforming mesh is placed below the valve, one above the mostly flat rim, and one above the neck. Several neighboring meshes will be sliding on each other's surface. This is handled by a special, ring shaped, structured mesh, which is one cell thick. Most cell data within will be affected throughout by the interpolation of the snapping.

The cell counts for different type of meshes are as follows: unstructured, static or translating meshes have a total of 125 k cells, deforming meshes count 300 k cells and the two ring shaped meshes handling surface sliding have 12 k cells, these sum up to 437 thousand cells.

The opening and closing of the valves is timed according to the movement of the piston. The movement of each five meshes belonging to the same valve is controlled by a single program object. Each of the three movement controlled adjusts the adaptive time step accordingly, so that layer heights before and after snapping are constant, which makes interpolation matrices also constant.

Most structural meshes have tetrahedral cells slashed from prism cells. The snapping and interpolation of these is discussed in [10]. For the ring formed mesh interpolations must be handled with care, matrices are calculated therefore beforehand [12].

C. Domain Decomposition

All tasks of mesh decomposition is mostly done using ParMETIS [19]. To keep implementation simple, one level of decomposition is done. The implementation is required to handle even several thousands of mesh parts, that can be of various types, and can reside on various processes.

The first implementation is assuming a fixed number of mesh parts, which can be partly or completely inactivated by the deformation algorithm. The data synchronization part is prepared to handle a possibly upcoming load balancing module. The synchronization handler awaits the following data:

1. Unique numbering of each mesh part.
2. Mapping of each part to the process rank currently handling it.
3. Common surface cell count for each neighboring mesh part.
4. Local indices of cells, whose data are to be transferred, for each neighbor.
5. Local indices of ghost cells to be updated with neighbor cell data.

For a specific load balance distribution of mesh parts among processes, the cell count to be communicated to every process can be calculated. As all inactive cells data and inactivity information is transferred, this cell count is constant, until mesh part distribution changes.

Cell data synchronization is done in the following manner:

1. Four separate buffers are allocated for sending and receiving cell data and inactivity data.
2. Send buffers are packed grouping data by process rank, and then by mesh part id-s.
3. Two calls to MPI_Alltoallv calls deliver the cell data to the designated processes.
4. Both receive buffers are walked synchronously. Only active cell data is updated to the ghost cell area.

The lists of mesh part cells to be synchronized, and ghost cells to be updated are calculated in the following manner:

1. Each mesh is generated and loaded by each process.
2. Synchronization cell lists are generated for these meshes by all processes.
3. Every mesh is partitioned following a predefined scheme, and intra-mesh synchronization cell lists are generated.
4. Inter-mesh synchronization cell lists are updated by partition mappings.

In the present work the following partitioning schemes are used for the different types of meshes.

1. All non-structured, static meshes are partitioned separately the usual way by ParMETIS to as much parts as processes.
2. Structured meshes always have a 2D surface, from which they get generated. This surface is partitioned to as much part as processes. All cells within the same column will belong to the same mesh part.

This scheme ensures perfect load balance for all processes, as even all calculations of snapping interpolations are distributed among the processes. However there is a great drawback on the fact, that the scheme does not consider communication cost.

There are a number of additional issues that require careful handling. The synchronization scheme of the multi-mesh surface around each valve is depicted on figure 4. As the valve is opening or closing, cells on both side of the valve rim, in diferent structured meshes get mutually activated and deactivated, meaning multiple cells may occupy the same physical space, of which only one is active. Only data from the active cell may be used for updating the appropriate ghost cell of the neighboring mesh of the piston crown.

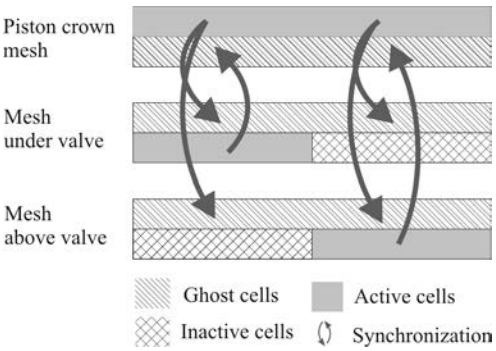

Figure 4. Synchronization scheme of the multi-mesh surface surrounding the two valves are shown. Although every cell data is transferred, only active cell data is written to the ghost cell area.

Another issue arises, if a mesh is connected to the deforming surface of another: the indices of the cells to be synchronized must be adjusted according to the layers snapped. A similar issue must be addressed within the interface mesh, where snapping slides cell columns along each other.

The final, minor problem is the crevice below the closed valve. As degenerate cells are to be avoided, these cells are rendered inactive as long as the valve is closed (see fig. 1). Neighboring meshes must be marked, so that the appropriate boundary condition is applied beforehand, so if inactive cell data is not updated, ghost cell data will remain valid.

The decomposition procedure is primarily validated by watching conservative variables in a fully closed system, where both intake and outlet ports are closed. A full

validation is also issued, where all data are written out up to a certain precision, and compared

D. Hybrid Implementation

Both MPI and OpenMP implementations will have their limitations on the pieces of HPC hardware at hand. Conventional OpenMP code is limited by the number of cores having access to the same virtual address space. Also, if MPI is used alone with traditional domain decomposition, the per-process cell count will be frittered away as a result of the modesty of the simulation mesh size. This will considerably increase communication cost, impacting speedup in the high process count range.

It is plausible to use multi level parallelization for the intra- and inter-node level separately. For inter-node communication MPI is the most feasible choice, as is multi-threaded OpenMP for intra-node parallelization. The implementation of multi-level domain decomposition with MPI-MPI parallelization is also a viable option, however only the first scheme is studied for now.

The MPI-OpenMP hybrid implementation is done the following way. Only one, unified code is developed, in which two preprocessing symbols are utilized: PARMOD_MPI and PARMOD_OMP will adaptively cut relevant code segments of MPI and OpenMP sections in and out. In this manner, defining or not defining the symbols above will result in a serial, OpenMP-parallel, MPI-parallel, or hybrid code. To avoid the unknown pragma warning, OpenMP pragmas are accompanied by a preprocessor macro that employs the _Pragma operator if PARMOD_OMP is defined, and is left blank otherwise. Nevertheless, this practice inhibits the use of certain profiling tools that depend on source code instrumentation.

The actual hybrid code development is abiding the rule that no MPI calls shall be made within OpenMP parallel regions. For every new feature added to the code the following steps are carried out:

1. The serial code is implemented, as well as tested in a predefined manner.
2. The OpenMP parallelization and validation is done for various thread counts. Also, some benchmarks are run to bar out performance pitfalls.
3. Appropriate domain decomposition and data communication is implemented with MPI calls. Validation is done for various process counts.
4. As no MPI calls are made within OpenMP parallel regions, compiling with both preprocessing symbols defined along with the necessary flags will result in a hybrid executable. Notwithstanding, validation is still carried out for various combination of process and thread counts, including the cases where either of them is one.

Experience shows that the larger or the more complex portions of features are added and parallelized, the harder are emerging bugs to track down. Within the present simulation, these features span from flow calculations within a single static mesh to flow simulation, mesh deformation, data interpolation among fifteen meshes with various traits.

III. BENCHMARKS

Time cost of the simulation algorithm is measured in a predefined way. As time stepping is adaptive, a specific number of explicit time step loops is considered, and is measured continuously. The average and relative error of 25 time sections are calculated. All results presented here have a relative error below 1%.

Calculations are done on two pieces of HPC hardware available for researchers of the Széchenyi University. Hardware details are shown in Table 1. MPI and Hybrid benchmarks are done on the “Plexi” cluster system, while many-core OpenMP benchmarks use the “Memo” SMP machine.

TABLE I. Hardware description

System Name	Plexi	Memo
Architecture	Cluster	SMP
Processor type	Intel Xeon X5650	Intel Xeon X7560
Cores / Processor	6	8
Processor / Node	2	8
# of Nodes	20	1
Total Cores	240	64
Ram / Processor	24 GB	128 GB
Total RAM	960 GB	1024 GB
Interconnect type	Quad Infiniband	QPI

Both systems have a 64-bit Redhat Linux Enterprise Server version 5.5 installed. On the cluster system benchmarks are queued using PBS, however, full nodes are reserved at all times. For compiling, gcc version 4.1.2 is used with libgomp 3.0, boost 1.42 and OpenMPI 1.4.2.

As the serial code uses the same procedure, as the parallel implementations, the unified code is compiled without defining the PARMOD_MPI and PARMOD_OMP sections, resulting in an actual serial program. Pure MPI benchmarks are carried out with the code compiled with PARMOD_MPI only, while pure OpenMP defines PARMOD_OMP only.

A. Scaling with Different Parallel Techniques

The first bunch of runs measure MPI, OpenMP and Hybrid scaling of the solution of the Euler equations on the four-stroke engine model. As the number of used nodes and number of processes per node greatly influences performance, the maximum performance is determined first for both MPI and hybrid implementations. For OpenMP, thread assignment is left to the operating system. Results and setups are shown in Table II.

TABLE II. MAXIMUM SPEEDUP AND # OF CORES

	OpenMP	MPI	Hybrid
Speedup	20,89	41,62	61,91
# of Cores	32	76	192
# of Nodes	1	19	16
# of Processes per node	1	4	1
# of Threads per process	32	1	12

At the time of measurement one of the cluster nodes had been down for a long time. Speedup curves are obtained by running four processes per node with MPI, and one process and 12 threads per node with Hybrid mode on fewer nodes, these are plot on Figure 5.

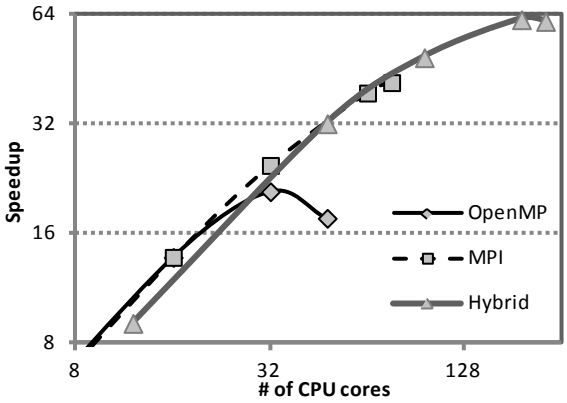

Figure 5. The fixed-size speedup is shown for OpenMP, MPI and Hybrid techniques as a function of the number of CPU cores used, on log-log scale. The actual data are shown with symbols, which are connected for better visualization.

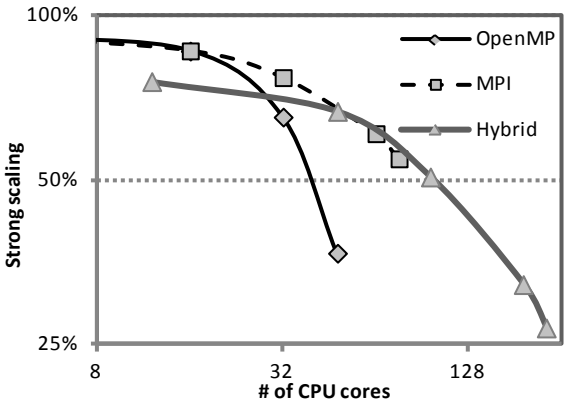

Figure 6. The strong scaling efficiency is shown for OpenMP, MPI and Hybrid techniques as a function of the number of CPU cores used, on log-log scale.

The strong scaling is also used to describe scalability; this is shown on Figure 6. The present form of implementation is not feasible to present weak scaling. The actual load per process can be indeed increased with the arbitrary increase of time steps, however it can be easily seen, that it will be similar to the strong scaling, and will present no new information.

Increasing cell count proportional to number of processes would prove more intriguing, however under this construction solvable.

B. Hybrid Performance of Different Cell Count Systems

It is worth investigating by all means, how increasing cell count will affect performance. Three meshes are generated and combined for this purpose. All three meshes are derived from the same 2D surface, which consists of regular triangles (see fig. 2). Several more layers are then generated by replicating the surface and moving it in the perpendicular direction. These layers are then connected to form a prism mesh, and finally every prism is appropriately cut to three tetrahedrons, as described in [10].

Setting the three meshes on top of each other, the middle one is considered deforming, and is squeezed down to one layer height in a harmonic motion. Its maximum volume is set to the sum of the other two meshes. So along the simulation, the top mesh will be stationary, the middle one will be deforming, and the lower mesh will be translating along with the lower surface of the deforming one.

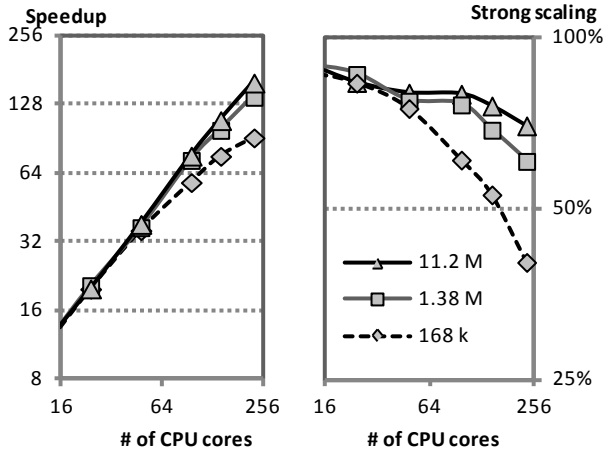

Figure 7. Speedup (left) and strong scaling (right) is shown for generated meshes with various cell counts as a function of the number of CPU cores used on log-log scale.

The three cell count mesh assemblies are obtained by doubling linear dimensions in all directions. Results for mesh sizes of 168 thousand, 1.38 million and 11.2 million are shown on figure 7. The beneficial effect of the increasing cell count on scalability is obviously shown, and can be considered unsurprising.

Comparing strong scaling on figures 6 and 7, it is expected, that a mesh assembly of size around 500 k generated with the method above will allow a scaling performance of about 50%. However, the combustion chamber setup reached just above 25%, which can be deemed acceptable for first run tests.

C. OpenMP Efficiency

It is highly misleading, that MPI performance is compared in a way, where the supplemental resources per process are more abundant than the resources each thread has in the hybrid run. To study the actual behavior, 7 nodes i.e. 84 cores are picked and loaded fully. The native MPI, and several hybrid configuration benchmark results are shown on figure 8.

It is to be noted, that the performance of the pure MPI run on 84 packed cores, a speedup of 16, is well below the maximum speedup of 62 on 76 cores. It is also to be noted, that multi-level mesh decomposition, that consider processes residing on the same machine can have far better performance. The later approach, however, could be also considered an MPI-MPI hybrid technique.

This naïve hybrid implementation adds at least a factor of two if fewer, and a factor of one and a half if most resources are available.

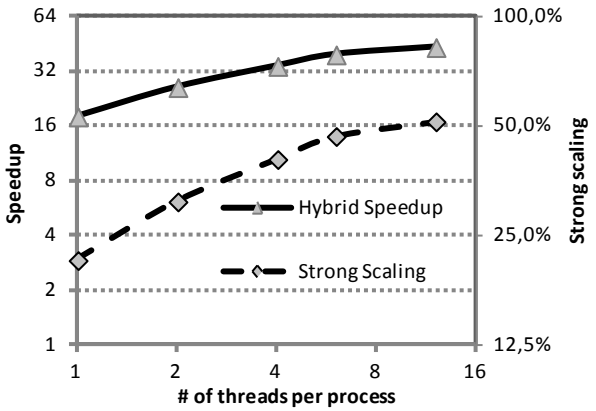

Figure 8. Speedup and strong scaling is shown for various hybrid configurations of 84 cores used on 7 nodes on log-log scale. The thread per process is shown from 1 (12 MPI process / node) to 12 (1 MPI process / node)

IV. CONCLUSIONS

The achieved speedup of 62 for the hybrid implementation can be considered encouraging. The factor four of the room left for speedup can be achieved by two factors. The first one is to implement further schemes of partitioning for structured meshes, taking also communication costs in account. Secondly, mesh migration and proper load balancing, that packs close mesh parts to the same node will minimize these costs further.

Regarding the snapping algorithm on structured meshes, several case-specific implementations were needed, that is not necessarily useful for different cases. As interpolation matrices can be calculated with a time cost proportional to the cell count, on-the-fly meshing seems to be more of an option.

It is clear, that multi level parallelization, which adapts to hardware environment, is needed for even modest sized clusters. Hybrid implementations are mandatory not only for petascale systems, but also for problems, that are not so obviously embarrassingly parallel.

ACKNOWLEDGMENT

The author thanks Zoltán Horváth and András Horváth for introducing him to this intriguing and challenging engineering problem. The author is also indebted to Gundolf Haase and Manfred Liebmann for extensive discussions on parallelization and optimizations issues. Also thanks to the group of Tamás Morauszki, especially Péter Mándli for providing the author with the necessary mesh files.

** Faculty of electrical engineering and computing, University of Zagreb, Zagreb, Croatia

Abstract - In recent decades there has been an exponential growth in quantity of collected data. Various data mining procedures have been developed to extract information from such large amounts of data. Handling ever increasing amount of data generates increasing demand for computing power. There are several ways of dealing with this demand, such as multiprocessor systems, and use of graphic processing units (GPU). Another way is use of field programmable gate array (FPGA) devices as hardware accelerators. This paper gives a survey of the application of FPGAs as hardware accelerators for data mining. Three data mining algorithms were selected for this survey: classification and regression trees, support vector machines, and k-means clustering. A literature review and analysis of FPGA implementations was conducted for the three selected algorithms. Conclusions on methods of implementation, common problems and limitations, and means of overcoming them were drawn from the analysis.

I. INTRODUCTION

Thanks to development of computer systems and its applications, the last several decades have been marked by exponential growth of collected data in all areas of human activity. To deal with this continuous and increasing influx of data it was necessary to develop computational methods for extracting information and discovering knowledge. Computational process of non-trivial information extraction is called data mining. Data mining makes use of methods from closely related fields such as statistics, artificial intelligence, machine learning, pattern recognition and databases.

With most data mining methods, the quantity of data directly impacts computational load. High computational loads occur because many problems include large quantities of data and require carrying out complex computations in many-dimensional space. The issue of computational load is a significant one. Quantity of collected data continually increases which implies that available compute power must increase to keep up with it.

Since CPU clock frequency no longer increases by the Moore's law, increase in compute power must be achieved by other means. One approach to the problem is using multi-core processors, multiprocessor systems, and computer clusters, where the program is still executed on general purpose CPUs. Another approach is using hardware accelerators, where the compute-intensive parts are executed on special purpose units. Currently available accelerator units are graphics processor units (GPU) and field programmable gate array (FPGA) devices, which are the focus of this paper. Both platforms have their advantages and disadvantages, and a review of their capabilities in compute-intensive applications is presented in [1].

FPGAs are integrated circuits designed to be configured by the user after manufacturing. An FPGA contains a matrix of configurable logic blocks and a hierarchy of reconfigurable interconnects that allow the blocks to be connected together. A configurable logic block contains look-up tables, multiplexers and flip-flops which together with interconnect allow performance of complex combinatorial and sequential functions and implementation of a wide variety of digital systems as well. Modern FPGAs also contain specialized memory, arithmetic, and communication blocks which enable more efficient implementations of digital systems. By allowing implementation of custom computational architectures FPGAs provide opportunities for exploitation of parallelism inherent in implemented algorithm.

This paper gives a review of current development in FPGA based hardware acceleration of select data mining algorithms. There are many algorithms developed for, and being used in data mining. From the multitude of algorithms Wu et al. in [2] present the top ten identified by the IEEE International Conference on Data Mining in December 2006. Of those ten, three have been selected for this survey: classification and regression trees, support vector machines, and k-means clustering. For the selected algorithms a survey of literature had been conducted, and found implementations have been analyzed.

This paper is organized as follows: Short introduction to selected algorithms is given in Section II; Results of literature survey are presented in Section III; Analysis of characteristics common to most FPGA implementations are presented in Section IV; Conclusions are given in section V.

II. SELECTED ALGORITHMS

To limit the scope of this survey, three algorithms have been selected from the ten identified by Wu et al. [2]. Data mining tasks of primary interest were classification and clustering as arguably the most common tasks. Of the top ten algorithms, five—C4.5, classification and regression trees, support vector machines, k-nearest neighbors, and naïve Bayes—are used for classification and two—k-means and expectation maximization—are used for clustering. As consequence of this count, two classification and one clustering algorithms were selected. The final criterion for selection was perceived amenability to fine-grained parallelization. The seven algorithms were analyzed with special attention paid to repeated use of same arithmetic and logic operations over multiple data,

and possibilities of pipelining the algorithms' implementations. From this analysis classification and regression trees, support vector machines, and k-means clustering emerged as algorithms with potentially highest gains from fine-grained parallelization.

A. Classification and Regression Trees

Classification and regression tree (CART) is a decision and regression tree learning algorithm. In decision trees the output is a prediction on class to which the data item belongs. In regression trees the output is a real number, and the tree represents an approximation of the function that maps input data to predicted outcome. One other well known decision tree learning algorithm is C4.5. Decision trees are easy to interpret, can readily be converted into a set of "if-then" rules, and can work with incomplete data.

Decision trees consist of nodes and leaves. Nodes represent simple attribute test which splits the data and determines branching of the tree into two or more branches. Leaves represent predicted class labels of the input data—the classification of the data. Classification is performed passing the data through the tree starting at the root node. Attributes are tested at each node and braches followed as determined by the test. When a leaf is reached its associated class label is the classification output.

CART algorithm constructs binary trees, and can work with categorical and numerical attributes. It works with "raw" data, i.e. it doesn't require preprocessing of data. The learning process is based on finding a test that defines the best split of the data. Test for categorical attributes is defined as "attribute $X_i = C$", and for numerical as "attribute $X_i \leq C$". Split quality is estimated by some information metric. Commonly used metrics are Gini impurity, and entropy. Once the attribute test giving the best split is found, the data is split according to it and procedure repeated recursively on the obtained subsets. To prevent overfitting, the splitting process can be stopped early by some rule, or pruning process may be run after the tree is built.

B. Support Vector Machines

Support vector machine (SVM) is one of the most popular methods for classification. The main idea of this method is finding a classification function that separates points from two classes from by finding a hyperplane that separates them optimally. For training set $\{\mathbf{x}_i, y_i\}$, where $\mathbf{x}_i \in \mathbb{R}^n$, and $y_i \in \{-1, 1\}$, classification function is of form:

$$f(\mathbf{t}) = \operatorname{sgn}\left(\sum_i \alpha_i y_i \, \mathrm{K}(\mathbf{t}, \mathbf{x}_i) + b \right) \qquad (1)$$

where: $\mathbf{t}$ is point (vector) to be classified, α_i are positive real constants, b is a real constant, and $\mathrm{K}(\mathbf{t}, \mathbf{x}_i)$ is a kernel function. Kernel function maps points from original space into a space where they become linearly separable. Some commonly used kernels are linear, polynomial, and Gaussian.

Hyperplane that optimally separates the sets is the one that maximizes the margin, i.e. which maximizes the distance from the hyperplane to the nearest vectors from both sets. For sets that cannot be completely separated the soft margin is introduced, which allows some level of misclassification of the training set. The points closest to the hyperplane are named support vectors, and they define the classifier. Finding classifier parameters α_i is a quadratic optimization problem. There are several algorithms for learning SVMs, e.g. sequential minimal optimization, and gradient projection.

C. K-means Clustering

K-means clustering is a simple iterative procedure for dividing a set of points into a predefined number k of clusters. Algorithm is executed on a set of d-dimensional vectors $\{\mathbf{x}_i, \mathbf{x}_i, \ldots, \mathbf{x}_n\}$, where $\mathbf{x}_i \in \mathbb{R}^d$. Clusters $\{S_1, S_2, \ldots, S_k\}$ are represented by their centers $\boldsymbol{\mu}_j$.

The algorithm starts by choosing k points from $\mathbb{R}^d$ which will be the starting values for centers $\boldsymbol{\mu}_j$. These points can be chosen in several ways, e.g. randomly of using some heuristic. After initialization of centers, the following two steps are iterated until the algorithm converges: (a) clusters are formed by assigning points to their closest center, and (b) new centers are found by computing the mean of all points in a cluster. Algorithm converges when points no longer change clusters. For distance metric, Euclidian distance is most common.

III. Literature Survey Results

A. Classification and Regression Trees

Survey of literature uncovered only one publication on FPGA implementation of decision tree learning. Narayanan et al. [3] have used FPGA to implement decision tree induction system for binary classification.

Gini impurity computation was implemented in hardware, as computationally most intensive part of learning process. One peripheral unit contains 16 Gini units working in parallel, as well as additional logic for finding the minimum Gini impurity and its associated data split. The peripheral unit is connected to the CPU's local bus. The implementation uses 16.16 fixed-point arithmetic. Algorithm is executed on a PowerPC CPU embedded in the FPGA device. The system is implemented on Xilinx Virtex-II Pro platform, with 100 MHz clock rate. The achieved speedup is 5.58× compared to pure software implementation running on the same platform.

B. Support Vector Machines

The research in hardware implementations of SVM is closely related research in embedded systems. As consequence using floating-point arithmetic is usually avoided in order to reduce energy consumption, and to reduce usage of logic resources in FPGAs. Computationally most intensive part of SVM training process is the matrix-vector multiplication.

Anguita et al. propose in [4] what was probably the first FPGA implementation of SVM training. In the paper they present a concise analysis quantization error and its influence on performance of SVM, with emphasis on fixed-point arithmetic and its influence. They present a

new SVM training algorithm suited for hardware implementation using fixed-point arithmetic. Algorithm has two phases which are executed alternately. In the first phase the quadratic optimization problem of finding parameters α_i with fixed parameter b is solved. In second phase the found parameters α_i are fixed and parameter b is found using bisection method. The training process is executed in hardware only. Calculation of sum $\sum_i q_{ij} \alpha_j$ is parallelized using up to 32 processing units. Using fixed-point arithmetic (8.8 to 16.13 formats), classifiers achieved performance comparable to the classifiers with floating-point training. The systems was implemented on Xilinx Virtex-II platform, with 19 to 35 MHz clock rate, depending on word width.

Pedersen et al. [5] have experimented with speeding up classifying with and training SVMs. Their focus was on accelerating scalar product computation by introducing hardware multiply-accumulate unit (MAC). The program was run on a hardware Java virtual machine [6] with the MAC unit attached to it. The system was implemented on Altera Cyclone platform, with 100 MHz clock rate. Speed-up achieved by using MAC unit was up to 59.8 % for training, and up to 6.5 % for classification.

Cadambi et al. in [7] present and advanced architecture of SVM training coprocessor. They use fixed-point arithmetic in 16.16 format, and on two of the datasets in 16.4 format. The system consists of a computer that executes training algorithm and an FPGA coprocessor for scalar product computation. Coprocessor contains 128 processing elements, which execute multiplication and accumulation, organized in 4 clusters, each containing 4 fields of 8 elements. Coprocessor uses local memory to store training set vectors, and uses buffers to enable the computation to run simultaneously with data transfer to and from the computer. Buffers are used to hide the data transfer latency and prevent stalling the coprocessor. The system was implemented on Xilinx Vitex-5 platform. Training time was compared to scalar and vector software implementations running on dual-core 2.2 GHz Opteron CPU. Speed-ups were 18.2× compared to scalar, and 6.5× compared do vector implementation.

Cao el al. in [8] present an implementation developed for Keerthi's training algorithm [9]. Keerthi introduces error matrix:

$$e_i = \sum_j a_j y_j \, \mathrm{K}(\mathbf{x}_i, \mathbf{x}_j) - y_j \qquad (2)$$

which is used for correction of parameters α_j, and b. To find the lower and upper bound of parameter b, a comparison is made over all e_i. This two parts of the algorithm—computation and comparison of e_i—are parallelized by means of error cache update (ECU) units. ECUs implement computation of error matrix elements and tracking of upper and lower bound of parameter b. ECU contains Gaussian kernel look-up tables, and MAC units for *ei* computation. Additionally, each ECU has its own local memory used for storing training vectors and temporary parameter values. The authors have investigated classifier performance achieved with different combinations of word widths and sizes of Gaussian kernel look-up table. Classifier with 16-bit arithmetic and table size of 1024 values, achieved classification accuracy equal to that of reference software classifier with floating-point arithmetic. The system was implemented on Xilinx Virtex-4 platform, with 75 MHz clock rate.

Papadonikolakis and Bouganis in [10] present an architecture that takes into account attribute data ranges of training datasets. They classify datasets as homogenous, in which dynamic ranges of attributes are equal, and heterogeneous, in which attributes have highly differing dynamic range, They identify evaluation of kernel functions as the most time consuming part of the algorithm and implement this functionality in hypertiles. Hypertiles implement scalar product using parallel fixed-point multipliers and a pipelined adder tree, followed by a floating-point kernel processor. For heterogeneous datasets each individual multiplier's arithmetic format is adapted to its input data format in order minimize its resource usage and to make the hypertile as compact as possible. The training vectors are stored in FPGA's local memory. Their approach requires training set analysis before implementing the hypertiles in order to extract attribute's data ranges. The system was implemented on Altera Straix III platform.

Wang el al. in [11] present a least squares SVM [12] implementation targeted for online SVM training in embedded systems. They partition the system into static and reconfigurable part. The static part contains embedded CPU, memory controllers and peripherals required for algorithm execution and communication with the host computer. They identify two parts of LS-SVM training algorithm as the most time consuming: the kernel matrix formulation and the least square problem solution, which are implemented as the reconfigurable parts of the system. The reconfigurable parts were loaded into the FPGA when the algorithm required them. The kernel matrix formulation is implemented with 8 kernel processing elements working in parallel. The least squares problem solver implements Cholesky matrix decomposition using 8 parallel processing elements for computing scalar product. The algorithm FPGA's external memory was used for storing intermediate results. The entire design uses single precision floating-point arithmetic. The system was implemented on Xilinx Virtex-5 platform with 150 MHz clock rate. Performance was compared to 2.93 GHz Xeon computer. Achieved speedups were in range from 6.02× to 218.45× for 512 to 8192 training samples.

C. K-means clustering

FPGA implementations of k-means clustering are primarily focused on image and video processing applications. Research is for the most part focused on computation of distance metric, which is the most computationally intensive part of the algorithm.

Estlick et al. [13] considered two modifications of the algorithm which could increase the available parallelism: alternative distance metrics, and smaller word width of input vectors. Alternative metrics were experimentally evaluated and the Manhattan distance—$\sum_i |x_i - \mu_i|$—was found to be the most suitable with respect to quality of

clustering and complexity of implementation. Experimentally was demonstrated that input data word width can be significantly decreased without adversely affecting clustering quality. The implementation used Manhattan distance metric, without word width decrease. FPGA uses two private external memories: one for storing pixel values, and the other for storing clustering results. The system is organized in a pipeline which executes distance computation, and finding minimum distance and associated cluster. Software that runs on host computer loads the pixels into the FPGA memory, and sets new cluster center values for each iteration. The system was implemented on Xilinx Virtex platform, with 50 MHz clock rate. The achieved speed-up was 200× compared to software implementation executed on a 500 MHz Pentium III computer.

Gokhale et al. [14] implemented k-means clustering for segmenting hyperspectral images. Their system was implemented on Altera Excalibur platform, which contains Altera Apex FPGA and an ARM CPU. They used two implementations: one with ARM CPU, and one with NIOS soft-core CPU. In the paper they demonstrate development of the system through several steps which illustrate influences of communication between CPU and FPGA, granularity of processing unit, and use of direct memory access (DMA) while executing the algorithm. Algorithm was implemented in several iterations, starting with completely software one and replacing the part of code that requires the most time to execute with a hardware unit. The final implementation uses hardware to execute computation of distances, uses DMA, and writes clustering results into a buffer where they are kept until read by the CPU. Distance computation unit contains 32 processing elements which work in parallel. The system runs on 33 MH clock rate. Speed-up achieved was 11.8×, compared to a 1 GHz Pentium III computer.

Wang and Leeser [15] experiment with adding a hardware floating-point division unit into the hardware implementation of the algorithm. They and a cluster association structure to the distance calculation and minimum distance tracking from [13]. They added accumulators that compute pixel sum for each cluster, and counters that track number of pixels in each cluster. New cluster center is computed by dividing accumulator value with counter value, which gives the mean of the cluster. Accumulators and cluster centers are working with fixed-point arithmetic. Hence the divider has fixed-point/floating-point conversion on its inputs and output. The system was implemented on Xilinx Virtex-II platform. Three implementations were compared: completely software, FPGA with division on CPU, and FPGA with division on FPGA. The Program was executed on a 3.2 GHz Pentium 4 computer. Compared to completely software implementation, for 50 iterations of algorithm a 11× speed-up was achieved, and for 1000 iterations a 174× speed-up was achieved. Differences in execution time for FPGA implementations with division on CPU and division on FPGA were negligible. The reason is that compared to distance computation, the division takes up a very small amount of execution time.

Sageusa and Maruyama [16], [17] implement real time k-means clustering for color images. The standard clustering procedure with Euclidian distance metric is augmented with kd-tree [18] filter which is used for finding cluster centers candidates for each pixel. Distance computation is then carried out only for this small set of centers. Kd-tree is implemented using memory banks. It's capable of finding centers for 4 pixels in parallel, and outputs 24 center candidates for each pixel. The system is realized as a three-stage pipeline. First stage contains the kd-tree, second stage implements square-of-distance computation, and third stage the cluster center for each pixel is found. Square-of-distance computation units are also used for kd-tree construction, which is carried out at the every iteration. The system was implemented on Xilinx Virtex-II platform, with 66 MHz clock rate. Performance was evaluated by clustering color image pixels into 256 clusters. Achieved performance for 512×512 and 640×480 images was at least 30 fps, and 20 to 30 fps for 768×512 images.

Covington et al. [19] use k-means clustering for document clustering. Documents are represented by vectors, where each dimension represents number of word occurrences in the document. Similar words are counted in the same dimension. Distance metric used is "cosine-theta" distance:

$$\cos\theta = \frac{\mathbf{x} \cdot \boldsymbol{\mu}}{|\mathbf{x}||\boldsymbol{\mu}|} \tag{3}$$

Words are translated into a 4000-dimension feature space using a hash based method. Document vectors and cluster centers are stored in external memory attached to the FPGA. The system contains three key modules. First module realizes distance computation, and consists of a square root, a scalar product, and a division unit. The module is complex and outputs one result every 294 clock cycles. One distance computation module is instantiated for each cluster center. Second module compares distances and assigns input vector to cluster with nearest center. Third module computes new cluster centers. The system performance was compared to a 3.6 GHz Xeon CPU. On Xilinx Virtex-E platform the system works with 80 MHz clock rate and achieves a 26× speed-up. On Xilinx Virtex-4 platform the system works with 250 MHz clock and achieves a 328× speed-up.

Nagarajan et al. [20] are taking a more general approach with intention to define patterns and models common to many algorithms, i.e. design patterns. The idea is that knowing and using these patterns will aid in system design. In their work they present a review of common communication and computing patterns. They begin hardware development with probability density function (PDF) approximation problem. By using structural similarities between algorithms they adapt the PDF approximation hardware to implement correlation computation, and k-means clustering, instead of implementing them from scratch. Implemented k-means clustering hardware is a three-stage pipeline consisting of: (a) square of distance computation, (b) finding minimum distance, and (c) cluster center update. The first two stages are similar to Saegusa and Maruyama's [17] implementation. The system was implemented and tested on Xilinx Virtex-4 platform. Achieved speed-up was 3.2×,

compared to a 3.2 GHz Xeon computer. The authors find the cause of small speed-up in low communication bandwidth between CPU and FPGA.

Hussain et al. [21] present an FPGA k-means clustering implementation for clustering microarray data. All parts of the algorithm are implemented in hardware, and distance computation is parallelized. Their implementation uses fixed-point arithmetic adapted to microarray data ranges. They use 5.10 format for distances, and 15.10 format for accumulators. The number of clusters is fixed to 8, hence 8 cluster distance units are used in parallel. Input data is stored in on-chip RAM. Several cores can be fit on single FPGA to perform clustering on different datasets in parallel. The system was implemented on Xilinx Virtex-4 platform, with 126 MHz clock rate for single core, and 124 MHz clock rate for five cores implementation. Achieved speed-ups were 10.3× for single core, and 51.7× for five cores implementation, compared to 3 GHz Core 2 Duo computer.

Singaraju and Chandy [22] implement k-means clustering on FPGA based network switches. The architecture allows data processing to be performed on the data as it flows through tha network in form of Ethernet packets. They implement all parts of the algorithms on the FPGA, and use floating point arithmetic for all computation. They parallelize distance computation, and finding minimum distance. Since used arithmetic operators are heavily pipelined, they use data element interleaving to hide the latencies. For single FPGA their system supports cluster parallelism, distances from multiple cluster centers are computed simultaneously for single data input. For multiple FPGAs, in addition to cluster parallelism, the system also supports data parallelism, where each FPGA operate on separate data points. Single FPGA is limited to up to 8 clusters in parallel. The system was implemented on Xilinx Virtex-II platform. For single FPGA, achieved speedups were up to 10× compared to Opteron 1.8 GHz computer. For multiple FPGAs performance was compared to parallel software implementation with equivalent number of nodes. Achieved speed-ups were up to 9×.

IV. Analysis of Implementations

Following features common to most implementations can be highlighted from this survey of FPGA based hardware accelerators.

For all implementations, the design process begins with algorithm analysis. Algorithm's hotspots are identified, and evaluated for possible gains in speed or execution time from implementing them in hardware. Most often, the hotspots are a short sequence of instructions that are looped through many times.

FPGA's clock rate is much lower than CPU's, usually one to two orders of magnitude lower. This is offset by exploiting available parallelism. FPGA can simultaneously execute several hundred to several thousand operations, depending on type of operation and its implementation.

FPGA implementations are usually pipelined. Apart from the additional "depth" parallelism provided by pipelining, separating the process into several smaller steps enables faster clock rate, and faster execution of algorithm. The algorithm is often rearranged or modified to enable more efficient pipelining.

Use of floating-point arithmetic is usually avoided. Floating-point arithmetic units are more complex and consume more FPGA resources than fixed-point arithmetic units. Higher per-unit resource consumption means less available parallelism because fewer units can be implemented in a single FPGA device. This is the main reason for using fixed-point arithmetic. Due to this constraint, a numerical analysis of algorithm is required to find sufficient range and precision of fixed-point number representation which will ensure correct results.

Only a few implementations perform the entire algorithm in hardware. In general, implementations are carefully partitioned into software and hardware part, and systems completely implemented in FPGA usually use a soft core CPU which runs the main program. This is a consequence of following factors: (a) control of algorithm flow is much easier to implement in software than by designing a hardware finite state machine for this function, and (b) parts of algorithm that execute infrequently can be left in software without adverse impact on overall performance.

A frequent problem in hardware implementations is communication with CPU and memory. In some cases, using hardware acceleration can actually decrease performance because the cost of moving data can be larger than the gain from faster hardware execution [14]. This problem can be tackled in several ways. First, by using direct memory access (DMA) where the CPU is taken out of the data transfer loop. The CPU then controls the data flow only by issuing commands for data transfer. Additional performance is gained by providing significant amount of private local memory to the FPGA, which then eliminates the need for frequent communication with shared main memory. And finally, data transfer latency can be hidden by using buffers, which enable processing of one block of data while the next block is being transferred.

Earlier implementations rarely used multiplication in FPGA since it was fairly expensive in terms of resources. Newer FPGAs families targeted for DSP applications include high-speed hardware multipliers and MAC units. Thanks to this development, later implementations benefit from using multiplication in FPGA hardware.

V. Conclusion

FPGA platform can be used as accelerator in data mining processes. It has great potential for use in data mining applications and computing in general, and especially in embedded systems. FPGA's flexibility and programmability enables implementation of optimal computer architecture for each specific task. From this literature survey we conclude that FPGA platform performs well as a hardware accelerator.

Results in this research area are significant, but we also noticed some important issues that prevent wider use of FPGAs in general purpose computing. First and most

significant is lack of mature high-level development tools. It is still very difficult to develop a hardware accelerator without knowledge of low-level details of hardware development, especially if full potential of FPGA is to be utilized. Second issue is a high cost of advanced FPGA platforms suitable for implementing data mining application. These issues currently limit the use of FPGA platforms to applications in which development effort and cost can be justified with gains in performance.

With development of high-level languages and synthesis tools, and development of hardware-software co-design methodology, designing for FPGAs could become much easier. Together with advancements in FPGA technology making the devices larger in terms of logic resources and providing more high-performance arithmetic blocks, the FPGA platform is expected to become more frequently used in data mining applications, as well as in computing in general.

***Abstract*— The Heston stochastic volatility model is one of the most popular models for the evolution of stocks and futures prices, which includes a stochastic process for the volatility. In practice it is usually enhanced by adding a Poisson jump process, which improves the overall correspondence with the observed behaviour of prices in the marketplace. The pricing of financial options by means of Monte Carlo or quasi-Monte Carlo methods can greatly benefit from the use of GPU computing due to the inherent parallelism of the computations. In this work we describe efficient parallel implementations of several popular option pricing schemes by using CUDA-enabled graphic cards. Our quasi-Monte Carlo algorithms make use of modifications of the Sobol and Halton sequences. The numerical and timing results demonstrate the excellent efficiency of our approach on the target computational platforms.**

I. Introduction

The financial option is a special type of financial contract that gives the owner the right, but not the obligation, to buy or sell an asset at a price that is pre-determined or defined with a special formula, on or before a given date. The financial options are a type of derivative financial instrument, because their value depends on the price of other financial instruments, for example stock prices, future contracts, interest rates. Options can be traded both on regulated exchanges or over-the-counter. The problem of numerical estimation of the option prices is one of the most important areas in Financial Mathematics [22]. Pricing options, that depend on the precise evolution of the prices of the underlying financial instruments, requires accurate simulation of stochastic processes that model this evolution. In 1972, Black and Scholes [7] published a paper, where they describe a simple model for pricing European options, assuming that the price is Brownian motion. This is the first standardized method for option pricing:

$$\frac{dS}{S} = rdt + \sigma dW_s, \tag{1}$$

where r is interest rate, σ is the volatility and dW_s is Brownian motion. There are several limitations of this model, but one of the most important is that the volatility is constant, contrary to the observed behaviour of financial markets, where volatility seems to be varying with time, exhibiting mean-reverting behaviour.

A. Heston model

One more precise model for pricing options was proposed by Steven Heston in 1993 [14]. The volatility in the Heston model is a time dependent stochastic variable, which follows a particular random process. The Heston model defines two stochastic differential equations - one for the price process and one for price variance:

$$dS_t = rS_t dt + \sqrt{\nu_t} S_t dW_s$$
$$d\nu_t = \kappa(\theta - \nu_t)dt + \sigma_\nu \sqrt{\nu_t} dW_\nu,$$

where S_t and ν_t are the price and its variance, W_s and W_v are correlated Brownian motions (with correlation coefficient ρ), ν_t is a CIR [9] process and converges to the so-called long-term variance θ, κ is the rate at which the variance reverts to θ and σ_ν is the volatility of volatility. It is important to note that the prices of European options under the Heston model can be obtained by a fast computational procedure. This allows efficient calibration of the parameters of the Heston model based on the observed prices of European options. However, it has been observed in practice that the Heston model does not produce a good fit for the observed European option prices with short times to expiration. In order to mitigate this problem, an additional Poisson jump process was introduced [8]. The price process now has additional term of the type $(J-1)dq$, describing jumps in the price with intensity λ and with mathematical expectation $\hat{\mu_j}$. In order to compensate for these jumps the term $\lambda\hat{\mu_J}dt$ is subtracted. The distribution of jumps is usually taken to be lognormal or double exponential. In this paper we assume lognormal distribution, thus adding three more parameters to the Heston model - λ and the expectation and standard deviation of the logarithm of the jumps.

Once the parameters of the Heston model are calibrated, based on the observed European options prices, one can compute the prices of other, more complex types of options. Options that depend on the whole underlying path of the price during the time period before expiration are called path-dependent. Examples of path-dependent options are the Asian options, where the payout of the option is determined by the difference between the average price of the underlying and the fixed strike price. Another type of path-dependent options are the barrier options. The barrier

options have payout similar to that of a European option, but it is paid for example only if a certain price is never reached during the time period under consideration. In this paper we consider the parallel implementation of algorithms that estimate numerically prices of path-dependent options. One of the most popular method for such estimation is the Monte Carlo approach [11], where one produces high number, N, of samples of the paths of the underlying and takes the average of the discounted option prices along each path. We implemented several well-known numerical schemes for adequate simulation of the Heston model with jumps, which can be categorized in two groups: schemes with bias and exact schemes. The schemes of Euler-Maruyama, Lord Modification [18], Milstein [17], Kahl-Jäckel [16] are schemes that are representatives of the biased schemes where there are two errors - from discretization of the continuous time process and the statistical Monte Carlo error. The scheme of Andersen [2] is representative of the exact schemes that use the properties of the CIR process and the variance is sampled using it's exact distribution, so there is only statistical Monte Carlo error.

B. Numerical Methods

In the following we describe these schemes for the classic Heston model. In all cases the addition of jumps process to the equation for the underlying leads to the same additional terms and similar operations during the implementation phase.

Euler-Maruyama: Uses the simplest method for solving Stochastic Differential Equations (SDEs).

$$S_t = S_s(1 + r\Delta t + \sqrt{V_t}Z_s\sqrt{\Delta t})$$
$$V_t = V_s + k\Delta t(\theta - V_s) + \sigma\sqrt{V_s}Z_v\sqrt{\Delta t}$$

Δt - time step;
$cor(Z_v, Z_s) = \rho$ - correlated random variables with normal distribution.

Lord Modification (Full Truncation): A scheme proposed by Roger Lord that aims to solve some problems observed in Euler-Maruyama scheme.

$$log(S_t) = log(S_s) + [r - \frac{1}{2}f_4(V_s)]\Delta t + \sqrt{f_5(V_s)}Z_s\sqrt{\Delta t}$$

$$V_t = f_1(V_s) + k\Delta t(\theta - f_2(V_s)) + \sigma\sqrt{f_3(V_s)}Z_v\sqrt{\Delta t},$$

$f_i(x) = x$ for $x \geq 0$. Where for $f_i(x)$ are chosen: identity $f(x) = x$, absorption $f(x) = x^+$ or absolute value $f(x) = |x|$.

Milstein: This scheme has improved order of convergence with respect to the previous two.

$$S_t = S_s(1 + r\Delta t + \sqrt{V_t}Z_s\sqrt{\Delta t})$$
$$V_t = V_s + \kappa(\theta - V_s)\Delta t + \sigma\sqrt{V_s}Z_v + \frac{1}{4}\sigma^2(Z^2 - 1)\Delta t$$

Kahl-Jäckel: This scheme is based on the discretization for the Heston model using Milstein scheme for the variance process and an alternative scheme for the price process.

$$\log(S_t) = \log(S_s) + (r - \frac{V_s + V_t}{4})\Delta t + \rho\sqrt{V_s}Z_v\sqrt{\Delta t}$$
$$+\frac{1}{2}(\sqrt{V_s} + \sqrt{V_t})(Z_s + \rho Z_v)\sqrt{\Delta t} + \frac{\rho\sigma\Delta t}{2}(Z_v^2 - 1)$$
$$V_t = \frac{V_s + \kappa\theta\Delta t + \sigma\sqrt{V_s}Z_v\sqrt{\Delta t} + \frac{1}{4}\sigma^2(Z^2 - 1)\Delta t}{1 + \kappa\Delta t}$$

In practice the variance process should never have negative values, but this is guaranteed only when $2\kappa\theta > \sigma$. Numerically if negative variance is achieved, it is set to 0 or mirrored over the axis, improving the overall accuracy.

Andersen: Andersen uses the system of SDEs in integral form and some of the properties of the variance process:

$$\begin{aligned} S(t) &= S(u)exp[r(t-u) - \frac{1}{2}\int_u^t V(s)ds + \\ &\quad \rho\int_u^t \sqrt{V(s)}dW_v + \sqrt{1-\rho^2}\int_u^t \sqrt{V(s)}dW_s] \\ V(t) &= V(u) + \kappa\theta(t-u) - k\int_u^t V(s)ds + \\ &\quad \sigma_v\int_u^t \sqrt{V(s)}dW_v. \end{aligned}$$

Andersen Scheme: The algorithm is based on sampling the variance process using distributions whose local moments match the original.

1. Generate a sample of V_t using distributions which local moments are the same as the original distribution;
2. Approximate the variance integral using drift interpolation:
$$\int_u^t V(u)du|V(s), V(t) \approx \Delta t[\gamma_1 V(s) + \gamma_2 V(t)] \quad (2)$$
if $\gamma_1 = 1$ and $\gamma_2 = 0$ we have Euler type scheme
if $\gamma_1 = \gamma_2 = 0.5$ we have predictor-corrector scheme;
3. Calculate the price using the following equation:
$$\begin{aligned} \log S(t) &= \log S(s) + r\Delta t + K_0 + K_1 V(s) + \\ &\quad K_2 V(t) + \sqrt{K_3 V(s) + K_4 V(t)}Z_s, \end{aligned}$$
where Z_s is random variable with normal distribution and K_i:
$$K_0 = -\frac{\rho k\theta}{\sigma}\Delta t$$
$$K_1 = \gamma_1\Delta t\left(\frac{k\rho}{\sigma} - \frac{1}{2}\right) - \frac{\rho}{\sigma}$$
$$K_2 = \gamma_2\Delta t\left(\frac{k\rho}{\sigma} - \frac{1}{2}\right) + \frac{\rho}{\sigma}$$
$$K_3 = \gamma_1\Delta t(1 - \rho^2)$$
$$K_4 = \gamma_2\Delta t(1 - \rho^2).$$

In order to augment all these schemes with a Poisson jump process for the underlying, one needs to sample 3 more random variables for each step. The first one is used to determine whether there has been a jump during the step. If the jump intensity is λ, then the uniformly distributed random

variable is compared with $\lambda\Delta_t$ to determine if a jump has occurred. If there has been a jump we sample the jump size from normal distribution. Thus we see that if there is a total of M timesteps, a Monte Carlo method will require $4M$ samples of either uniformly distributed or normal variables for one path, i.e. $4M$ is the *constructive dimensionality* of the algorithm. This means that the problem can be considered as an integration problem for a function with $4M$ variables. This consideration enables the use of quasi-Monte Carlo methods, where instead of random numbers one uses quasi-random points with good distribution in the respective $4M$ dimensional unit cube.

The high-speed implementation of Monte Carlo or quasi-Monte Carlo methods for option pricing is of high importance because of the increased use of options and other derivatives in trading and the undesirable consequences of inaccurate pricing. The current trends in HPC have established the use of graphics cards as a good alternative of regular CPU processing because of their power and space efficiency. In the next section we describe our particular implementation of the Monte Carlo method and the quasi-Monte Carlo methods with the scrambled Sobol and modified Halton sequences, targetted at GPU processing and suitable for use in parallel settings. In section 3 we describe our parallelization approach and in section 4 we show numerical and timing results, obtained with our codes.

II. Modular implementation of MC/QMC algorithms for option pricing on GPUs

All of the schemes outlined in the introduction require sampling of pseudorandom or quasi-random points in order to generate the path of the underlying along the timesteps taken. Our target computational platforms are equipped with the CUDA version 4.0 and support double precision arithmetic. For the Monte Carlo version, we used the default CURAND pseudorandom generator available from the installation. For the quasi-Monte Carlo version, we use one point in the $4M$-dimensional unit hypercube to sample $4M$ uniformly distributed variables. Whenever a normal variable is used in the schemes above, we utilized the inverse function method. Thus in order to sample N paths we need N quasi-random points from the $4M$-dimensional unit cube. One of the most popular families of low-discrepancy sequences are the sequences of Sobol and Halton. Typically they are never used without modification in schemes as the ones describe above, because they include the origin of the coordinate system and they present other potential problems, e.g., bad distribution of some two-dimensional projections. That is why some modifications of these sequences are used in practice. For the Sobol sequence the process of scrambling, proposed by Owen [20], offers theoretical and practical advantages. In our previous work [6] we show how the generation of such sequences can be done efficiently. We also developed fast generation routines for the modified Halton sequences, introduced by Atanassov in [3], where a favorable estimate of the discrepancy of the modified sequence suggests that it can be better in practical integration problems than other well-known sequences.

The total number of timesteps can be rather high in practical applications, which means that one has to be able to use high-dimensional sequences. In [4] we give links to the coefficients that are used in the modified Halton sequences when the first 16384 prime numbers are used. The directional numbers, provided by [15], allow generation of the points of the scrambled Sobol sequence in 12500 dimensions.

The computation of options is divided in two stages. In the pre-computing stage we choose which GPU device will be used by the corresponding host thread. We initialize the CURAND generator, for the Monte Carlo method, or pre-compute some coefficients that are necessary for the fast generation of Sobol or Halton sequences, for the quasi-Monte Carlo method. The actual computation consists in multiple invocations of the option pricing kernel on the GPU. We have fixed the number of GPU threads per block invocation at 256 and we have found that the size of the grid is not so critical for the performance. In practice we used 512 for this size. Thus one kernel invocation samples 131072 paths. We have found that there is certain register pressure, so that in some situations the option "–maxrregcount 64" is required during compilation for correct results. These two stages were implemented in the CUDA-extended C++ dialect supported by NVIDIA, with the main routines exported as functions callable from C.

III. Parallelization Approach

In previous section we included the choice of GPU device by each host thread in the pre-computing stage. This is an important step because the GPU resources that one has access in practice usually include more than one GPU device per host system. One of the GPU-enabled high-performance systems that we have access to is an HP ProLiant SL390s G7 Server with four M2090 NVIDIA Tesla GPUs. The M2090 GPUs are relatively new and are targeted at seismic processing, biochemistry simulations, weather and climate modeling, signal processing and data analysis, etc. The system has a total of 2048 computing cores for GPU-enabled scientific computations (512 cores per GPU), resulting in peak performance of 2.6 TeraFLOPS in double precision. The system has ECC memory. Our tests showed that turning off the ECC gives approximately 5% faster execution. For example, one of the tests finishes in 41.6 seconds with ECC turned on and in 39.7 seconds when the ECC is turned off. When we consider the task to parallelize our algorithm for one target multi-GPU system, we thought the most natural way would be to have one host thread for each GPU. The easiest way to distributed the work among GPUs would be static distribution, but we discarded it because it will not be appropriate for systems that have different types of GPU on board. That is why we developed a dynamic load balancing solution with one main thread responsible for distribution of work/gathering of results and the other threads computing blocks of paths. Since we had the main two functions related to the two-stages of our algorithm callable from C, we had

certain flexibility in how to implement this part. Our first implementation was done using the D programming language [1], because it supports clean threading model where the threads communicate mostly with message passing. We did not use any shared data and we made the worker threads to communicate only with the master thread, sending and receiving inputs and results of the computations. This implementations is useful on single host systems. However, we also have access to a cluster of GPU-enabled machines, each one equiped with NVIDIA GTX 295 cards which motivated our MPI-based parallel implementation. In order to facilitate code-reuse we simply replaced the main routines of the above implementation with MPI-based implementation of the master-slave paradigm, without any changes to the CUDA parts. This implementation is widely portable, because it only needs CUDA and MPI, and implements again dynamic load balancing, i.e., it is usable in heterogeneous situations. Nevertheless, we thought that there are practical situations when it is not possible or practical to start one MPI program accross the whole set of resources available, for example due to firewall or other administrative restrictions. For this case we developed a framework where only one of the processes needs to have inbound network connectivity. This (main) process binds to a UDP port and waits for incoming communications. A client process is started by the user, submits all the work to be performed to the main process and waits for all the results to arrive so that it can process them and produce a final estimate of the option price.

The worker processes are started on each target system and launch one gpu-worker thread for each logical GPU device on the host. The communication with the master process is done via UDP and the internal communication between threads is done with messages. This final parallelization framework has the advantage that only one host, which does not have to be GPU-enabled, must be visible to all the others, e.g., by having public IP address. It also uses smaller number of processes when multi-GPU hosts are interconnected. One of the main use cases to prefer the framework versus the MPI-based implementation would be when GPU-enabled hosts from one or more cloud providers are interconnected with locally-owned resources. It is obvious that in such a situation it is not natural to try to establish MPI connection between all such hosts, especially if their number becomes large enough. Another advantage that can be exploited in grid setting is that the framework does not need all the resources to be connected at the same time. Thus if some of the workers are started from grid jobs, they will be able to connect and contribute to the final result.

In general we found that the performance of the MPI and the threading-based parallelization approaches when applied on the same host was similar, without clear advantage in one way or the other and thus the choice will be based on ease of use. In the next section we present numerical and timing results, obtained with the UDP-based framework, which demonstrate that our implementation achieves excellent parallel efficiency.

IV. NUMERICAL RESULTS

Numerical schemes were implemented to work on GPU using NVidia CUDA framework [10]. This architecture allows the GPU processor to be turned into highly parallel multi-core system capable of executing hundreds of parallel threads. The CUDA topology is based on grouping the threads in blocks and run them parallel, in our case the most efficient scenario was to use 512 blocks with 256 threads that allowed us to execute 65536 threads at one call of the gpu function (the kernel function). In this scenario every thread is simulating one path from the Monte Carlo algorithm and in the quasi-random case use the coordinates of one point from 4M-dimensional quasi-sequence as source of random numbers (M is the number of time intervals). All of the schemes are implemented using the standard CURAND - pseudo-random number generator and generators for Sobol'(with Owen scrambling [20]), [6], [12], [19], [21] and modified Halton (proposed by Atanassov) sequences [3], [5], [13]. For test case it was chosen a example of European option [8] with period 1 year and the following parameters:

$$r = 3.19\%, \kappa = 6.21, \theta = 0.019, \sigma_v = 0.61, \rho = -0.7,$$
$$S_0 = 100, V_0 = 0.010201, \lambda = 0.1, \mu_j = 0.1, \sigma_j = 0.2.$$

In Table I it is shown the error using Monte Carlo method with CURAND generator and different schemes, applied for evaluation of European options with the above parameters. From the results we can see how the schemes of Kahl-Jäckel-Milstein and Andersen are far more accurate than the other two. That is why for our further investigation we only consider these two schemes.

In Table II one can see the average acceleration in times when the schemes are implemented on GPU (NVIDIA GTX 295) vs standard CPU-based implementation (CPU Intel Pentium Core i7, 2.6 GHz). We can see that in all cases there is substantial improvement. The Andersen scheme has more logical operations and this affects its GPU-based implementation. We should point out that the GTX 295 card is the slowest of those that we tested, when considering double precision performance, because it has 8:1 ratio of maximum double versus single precision operations per second.

In Table III we compare the accuracy of quasi-Monte Carlo methods implemented using scrambled Sobol se-

	2^{21} paths	2^{25} paths
CURAND	9.22E-04	4.15E-04
Halton	3.22E-04	2.56E-05
Sobol	4.14E-04	1.03E-04

TABLE IV

PATHS PER SECOND WHEN COMPUTING A BARRIER OPTION

quences and Halton sequences with standard Monte Carlo method, for the Andersen scheme. The option being evaluated is an Asian option with strike 100. We show the relative error for 52 time steps, depending on number of paths. In this case the Halton sequence clearly outperforms, suggesting that it should be used even if the computation speed is much smaller, because typically to achieve two times increase in accuracy one has to perform 4 times more computations in Monte Carlo.

The results in Table IV show the computational speed, measured in sample paths per second, when using different Schemes (Andersen vs Kahl-Jäckel-Milstein) and different types of pseudorandom or quasi-random numbers. Both scrambled Sobol and modified Halton sequences were implemented and tested. The results show that production cards like M2090 or M2050 have much better performance due to their better support for double precision operations. The Andersen scheme runs slower, but in most cases it has much better accuracy, so it is justified to use it instead of the Kahl-Jäckel-Milstein, especially for smaller number of time steps. The use of scrambled Sobol and modified Halton sequences results in much smaller speeds than the use of the default CURAND generator. However, looking at the results in Table II and taking into account that to improve the accuracy of a Monte Carlo computation N times one has to sample N^2 times more paths, we conclude that it is justifiable to use the scrambled Sobol or especially modified Halton sequences in order to arrive at a more accurate result for fixed computational time.

The results about parallel efficiency in Table V show that the case of parallel implementation on a single host machine is the easiest one. The results for the SMP implementation are computed on the workstation, equipped with 4 M2090 cards and show excellent efficiency of close to 100%, which is to be expected since the communication is achieved over the host memory. The second line shows results of

	Number of threads	Maximum expected	Achieved	Efficiency
SMP	2048	1151	1134	0.99
MPI	1920	368	327	0.89
UDP	4864	1974	1812	0.92

TABLE V

MAXIMUM EXPECTED AND ACHIEVED SPEEDS, MEASURED IN PATHS PER SECOND, WHEN COMPUTING IN PARALLEL

the MPI implementation, running on the cluster of 4 PC servers equiped with GTX 295 (8 logical GPU devices). The theoretical speeds are computed as corresponding multiples of the single device speeds. The UDP-based work distribution scheme has been run over all the available GPU-enabled servers, adding two M2050 from Amazon EC2. The theoretical speed in paths per second is computed as a sum of all the speeds of all available GPU computing devices. The achieved speed is computed by division of the total computed paths by the total wall clock time. We observe that the efficiency of the UDP-based dynamic load distribution scheme is more than 90% and that the scheme is competitive when compared with the MPI-based parallelization approach, especially considering the fact that we used a heterogeneous system with quite varying speeds for the sub-components.

V. CONCLUSION

As it is shown in the numerical results two important results are achieved. Our parallel implementation of quasi-Monte Carlo algorithms for option pricing is suitable for high number of timesteps, in the order of thousands and has excellent parallel efficiency. The use of modified Halton sequences is promising for the case of pricing financial derivatives. The framework that we developed for the distribution of the work among heterogeneous GPU-based resources can be used in other types of problems where Monte Carlo or quasi-Monte Carlo methods can be used. In the future we plan to further extend this framework and make it easier to deploy on the target computational resources.

Analyzing User Click Paths in a Wikipedia Navigation Game

***Abstract*—Due to the enormous success of Web search technology navigation became only a second-class information seeking strategy on the Web. However, numerous studies highlight the importance of navigation as an alternative information retrieval technique to search. These studies provide evidences that the most efficient information finding occurs in the settings where search and navigation seamlessly integrate and complement each other. Recently, the research community has also recognized the importance of understanding the human navigation behavior since the knowledge on how users navigate helps in designing optimal navigation structures. In this paper we try to gain more insight in how users navigate towards a known target page in Wikipedia. To that end, we conduct an initial analysis of user click paths from a Wikipedia navigation game. In addition, we compare the structure of Wikipedia navigational paths with the structure of search paths in social networks and routing paths in general complex networks.**

I. Introduction

In the hypertext systems of the first generation navigation was the primary method of retrieving information. The Web, as a special type of a hypertext system, adopted navigation from its very beginning [1]. Nonetheless, whereas in traditional hypertext systems the content providers always exercised the complete control over the system navigational structures making it possible for them to design efficient and optimal navigation structures, on the Web – because of its technological and social properties – the content providers have never possessed that control. The practice of Web links creation has always been governed by both the underlaying technology and social processes occurring on the Web such as e.g. preferential attachment [2]. As a result, the navigational structures on the Web emerge in a decentralized manner. Moreover, in the early days of the Web these decentralized navigational entities exhibited exponential growth and thus users very soon were not able to handle neither their sheer size nor their complexity (cf. the discussion by Jacob Nielsen on this topic [3]). Therefore, the focus of the Web developers moved to search technology as an alternative information retrieval method.

However, from the information retrieval perspective navigation represents a complementary information seeking strategy, which is for certain kind of problems much more efficient than keyword-based search. For example, in cases where users do not know about the existence of a relevant document or can not formulate their information need in a couple of keywords [4] navigation is preferred and more efficient than search. Some other researchers accentuated the importance of navigation and the complementary nature of navigation and search. For example, Teevan [5] suggested that the participants of their study on the user behavior in locating information on the Web commonly employed so-called direct situated navigation, or orienteering. In orienteering, information is reached through a large first step, e.g. a search query and then through a number of smaller steps by means of browsing. A recent study that investigated user behavior in Web search [6] showed that only few users satisfy their information need with their first search query. Instead, users visit one of the first search results, follow links on that result page, backtrack, follow some other links, then frequently refine their search, and so on.

A recent large-scale study on user behavior on the World Wide Web also supports these results. In this study authors estimated the fraction of users following links as opposed to "teleportation" [7]. More precisely, the study empirically investigated teleportation parameter α [8] that was introduced by Page and Brin in their PageRank algorithm. The teleportation parameter models the probability that users do not follow a link from a currently displayed document, but that they rather "teleport" themselves to an arbitrary document by e.g. typing a new URL into the browser address bar or by typing a keyword into the browser search toolbar. The original Google design assumed $\alpha = 0.15$ due to computational practicability but also due to the expectation that teleportation on the web takes place at this rate – (in other words: Page and Brin estimated that users follow links in 85% of cases). The empirical analysis of the teleportation parameter [7] shows a slightly different picture in navigational behavior of modern Web users – on the general Web, users on average follow links in around 65% of cases. Although this number is smaller then the original assumption by Page and Brin, the findings still provide strong evidence for the significance of navigation on the Web.

Although the importance of navigation seems indisputable we, as a research community, know very little about how users navigate. There are some initial empirical and theoretical studies on user navigation behavior (we mention some of these in Section II). However, many questions regarding navigation remain unanswered, such as (i) what are the mechanisms that govern user navigation in e.g. decentralized information networks, (ii) what are the structural patterns in user navigational

paths, (iii) what strategies users apply when they navigate, (iv) how does the underlying network structure influences the strategies, patterns, and navigation mechanisms, to mention only a few.

In this paper we try to provide some initial thoughts on how to answer those questions. User navigational behavior is a complex process that is dependent on various factors such as user background knowledge, current information need, information and navigation structures provided by the system, network structure, and so on. The goal of this paper is to make a small initial step and shed light on some of these factors. To that end, we analyze click paths of users who participated in a Wikipedia navigation game[1]. Thereby, the focus of our analysis is on the structure of these click paths.

II. Related Work

One of the first studies that investigated the user navigational behavior on the Web was conducted by Huberman et al. [9]. In that study, the authors introduced a model of user navigation that assumes that users navigate to yet another Web page as long as the value of the next page exceeds a certain threshold. The result of this model is a probability distribution of the number of pages that a user visits on a Web site. The empirically obtained probability distribution follows a power law where the majority of users visits only a few Web pages and only a few users visit many pages. Thus, the value of navigation to a new page decreases as a power law with each new page that users visits.

Along the lines of these results, Pirolli developed the notion of information scents [10] and information foraging theory [11]. An information scent is an indicator of the value of each new page that a user might visit. The theory states that as long as information scent of a page is high the users are willing to explore that page. Information scent varies not only from a user to a user but also from one information retrieval task to another. For instance, if a user aims to reach a Web page on relativity theory then Albert Einstein's Wikipedia page possesses a high information scent, however if the user wants to reach homepage of a soccer club in England then the information scent of the page on Einstein is rather low. Thus, according to information foraging theory user behavior in information systems is guided by a constant estimation of the cost and the value of a particular information item in respect to the current information retrieval task.

Research on navigation in complex networks was initiated by the problem of search in social networks, which in turn originates in the famous small-world experiment conducted by Milgram [12]. In that experiment randomly selected persons from Nebraska got a letter for a target person – a stockbroker in Boston. The experiment participants were then instructed to pass the letter to that target person through their social networks, i.e. they were allowed to send the letter only to a person whom they knew on the first name basis. Additionally, they were required to justify their decisions by writing down the reasons why they selected a particular person. In most cases the search strategy was based on geography or profession, i.e. the experiment participants either sent the letter to someone whom they knew in Boston or to a person that worked in the financial industry. The striking result of the experiment was that those letter chains that reached the target person were very short – the average chain length was only six. Thus, the population of the United Stated constituted a "small world".

Apart from the findings that humans in the US social network are connected by short paths, another important result of that experiment was the conclusion that humans are able to find such short paths with only local knowledge of the network, i.e. humans can efficiently perform *decentralized search*. Kleinberg concluded that social networks possess certain latent structural properties known to humans. This *background knowledge* of the network structure allows us to find a short path to an arbitrary person [13], [14], [15] even in the absence of global knowledge. Basically, Kleinberg argued that humans utilize the notion of similarity or distance between nodes in a network and that they base their search strategies on that similarity, e.g. always selecting the most similar node to the target node as the next step in their search. Kleinberg represented such background knowledge as a hierarchy of nodes, where more similar nodes are situated closer to each other in the hierarchy. Also, Watts [16] introduced the notion of social identity as a membership in a number of social groups organized in multiple hierarchies and showed that an efficient decentralized search algorithm exists in the cases where humans consult those hierarchies while they search.

In [17] the authors extend the notion of distance as introduced by Kleinberg to a notion of *hidden metric spaces* which steer both navigation in the network and the network formation and emergence of network structural properties such as power-law degree distributions and high node clustering. The authors then connect some observable emergent structural properties of a network with its navigability by defining a region of navigable networks in two dimensional space with clustering-coefficient [18] and power-law exponent as dimensions. In such hidden metric spaces nodes are identified by their coordinates – distance between nodes is their geometric distance in a particular metric space. An interesting research question is the structure of such hidden metric spaces that underlie observable networks. In [19], the authors introduce a model with the circle as a hidden metric space and show its effects on routing in the global airport network. In [20] the authors discuss hyperbolic geometry as a hidden metric space whereas in [21] the authors apply hyperbolic geometry as a model of the hidden metric space of the Internet and design a novel greedy Internet routing algorithm.

III. Dataset and Experimental Setup

A. Wikipedia Network

In this paper we analyze the dataset containing click paths of users of the Wikigame. Wikigame is a navigational game where users navigate from a randomly selected Wikipedia page to another also randomly selected Wikipedia page. The only

[1] http://thewikigame.com/

possibility to reach the target page is by clicking links (the search field is e.g not visible during the game). The complete Wikigame dataset contains about 1 million games – around one quarter of these games users finished successfully, i.e. they were able to reach the target page. In this paper we concentrate our analysis only on those successful click paths – we analyze the structure of these paths.

For the purpose of this analysis we also investigate the underlying decentralized Wikipedia network. To that end, we downloaded a complete Wikipedia dump of the English version from January 4th 2012[2]. We then constructed a network where Wikipedia pages are represented as network nodes and hyperlinks between those pages are represented as links connecting network nodes. There are various Wikipedia dumps and various possibilities to construct such a Wikipedia network. For example, there exist different types of Wikipedia pages, as well as different types of hyperlinks. Page types are defined by so-called namespaces, with standard Wikipedia pages belonging to the main namespace, and media objects such as images or videos belonging to file namespace. There are namespaces for discussion of the page and media content called talk namespaces. Further, Wikipedia user pages belong to the user namespace. There is also a special namespace called category namespace where Wikipedia category pages are situated. Because the majority of the click paths that are available in the Wikigame dataset contain visits to either standard Wikipedia pages, media objects, or category pages we selected only those page types for the network construction. The final Wikipedia network contains 10 million nodes (10286335) and around 250 million links (254650201).

B. Structural Analysis

Before we start with the analysis of click paths we perform the structural analysis of the Wikipedia network. This structural analysis contains the following steps.

Small-world properties. According to Watts [18], a small-world network is a navigable network that is highly connected and in such a network each pair or almost each pair of nodes is connected by a short path. More formally, a navigable network posses a large connected component (typically called giant component) that contains a huge majority of the nodes and such a navigable network exhibits a diameter (the longest shortest path in the network) that is proportional to the logarithm of the number of network nodes:

$$D \propto logN. \tag{1}$$

Alternatively, this second property is often expressed in terms of the average shortest path or in terms of the effective diameter, which is the longest shortest path under which 90% of nodes are reachable from each other.

Clustering and Network Heterogeneity. Another two network structural properties that are commonly observed in navigable networks are high clustering and degree heterogeneity. In highly clustered networks there is a large number of closed triads, i.e. in such networks the probability that two nodes are connected in cases when they share a common neighbor is higher than in e.g. random networks. For example, social networks are typically highly clustered as the probability that a friend of a friend is also a friend is high since humans tend to connect with people similar to themselves. It has been shown [18], [22], [17], [19] that such high clustering combined with a few so-called long-range links is necessary for establishing network navigability.

Additionally, many real-world networks exhibit heterogeneous degree distributions. In particular, power-law distributions are very common (see e.g. [23], [24], [25], [26]). Such networks have a few of highly connected nodes called hubs and many nodes (the long tail) with only a few links. In [27] the authors analyze and show the importance of hubs for navigation. In particular, the authors present an algorithm for searching in power-law networks that in the opening phase of search applies a simple strategy – the algorithm proceeds along increasing degrees and reaches very quickly one of the hubs. As hubs have many connections the probability of reaching the destination node from a hub is higher than reaching that destination node from a low degree node. The authors also analyze the time complexity of such an algorithm and show that the time needed to reach the destination node is sub-linear.

In [19] the authors establish a connection between the power-law exponent, clustering coefficient and the network navigability. By simulating navigation in networks generated with different values of power-law exponent and clustering coefficient the authors identify a region of navigable networks in this two dimensional space. Additionally, they show that many real-world networks are efficiently navigable as the observed values of the power-law exponent and the clustering coefficient are situated within the navigable region.

Apart from in-degree (k_{in}) and out-degree (k_{out}) distributions we also analyze the $\frac{k_{in}}{k_{out}}$ distribution. This ratio captures the "flow" of links towards and outwards of a node and can be a better estimator of the node importance for navigation. In [28] the authors apply this ratio among other measures to quantify the hierarchical level of nodes. Although very simple this ratio performs good and outperforms some other more complex measures such as PageRank [8] or HITS [29].

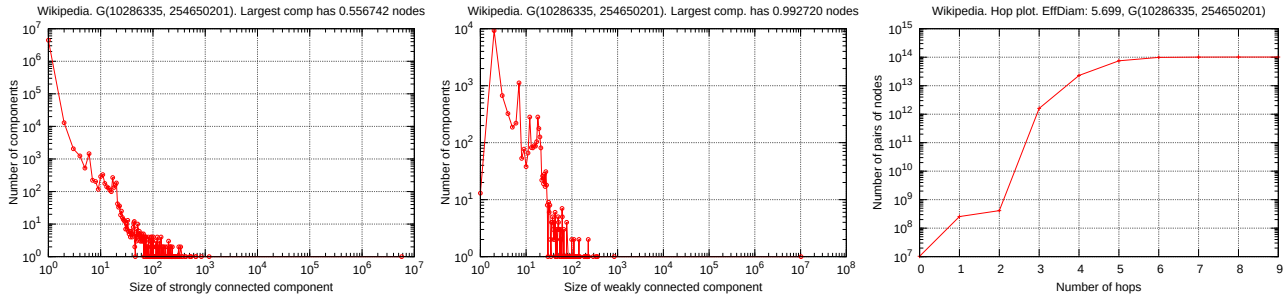
C. Click Path Analysis

In the second part of our analysis we turn to the click paths. This analysis phase contains the following steps.

Distribution of Click Path Lengths. First, we analyze click path length distribution. We are interested here in the ability of users to find short paths in the network in the case when those paths exists.

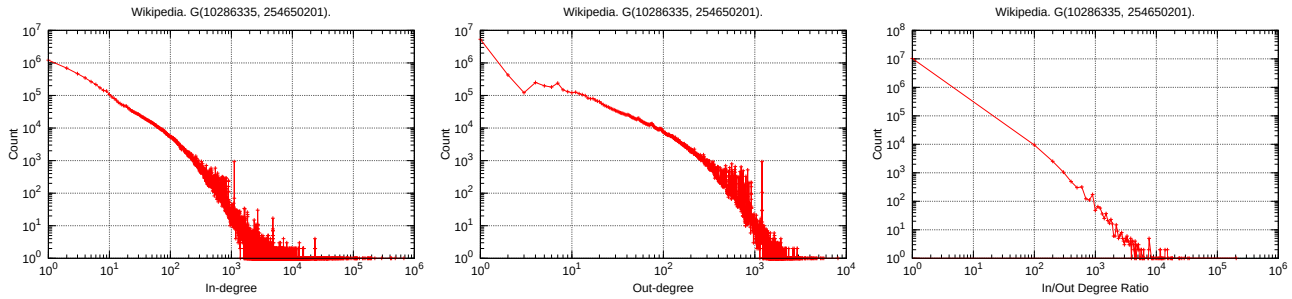
Degree Distributions of Visited Nodes. We start the click path structure analysis by investigating the degree distributions of visited nodes. With this analysis we shed light on the relative importance of nodes of different degrees for the user navigation. We also compare these distributions with the results from similar studies dealing with search in other types

[2]http://dumps.wikimedia.org/enwiki/



(a) SCC Distribution (b) WCC Distribution (c) Hop Plot

Fig. 1. Small-world network properties in Wikipedia network. The network is highly connected – the largest strongly connected component includes around 55% of nodes (left). If we ignore the link direction the largest weakly connected components contains more than 99% of nodes (center). Wikipedia nodes are connected by short paths – the effective diameter is less than 6 (right).



(a) In-Degree Distribution (b) Out-Degree Distribution (c) In/Out Distribution

Fig. 2. Degree distributions in Wikipedia network. Degree distributions follow, at least in certain regions, power-law. Nevertheless, the distributions are clearly skewed and heterogeneous. They show the existence of the hubs and the long tail of nodes with low degrees. In the right figure we plot $\frac{k_{in}}{k_{out}+1}+1$ distribution to correct for division with zero and plotting on the log scale.

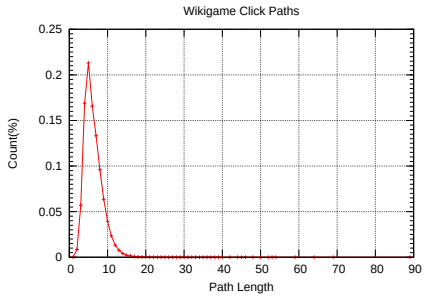


Fig. 3. Distribution of click path lengths. The distribution is similar to e.g. original small-world experiment [12]. This can be an indicator that user navigation in information networks follows similar principles as human search in social networks. Users are typically very efficient and can find short paths quickly. The average click path length is $\bar{l} = 6.27$ with standard deviation $\sigma = 2.42$.

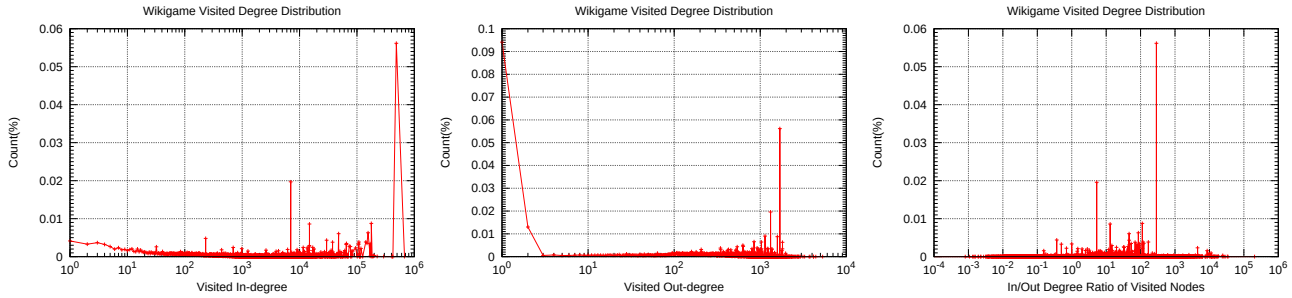
of networks, e.g. [27], [12], [19]. Finally, we also analyze the $\frac{k_{in}}{k_{out}}$ distribution.

Navigation Patterns. In [19] the authors observed a navigational pattern in complex networks that consists of two phases. In the first phase search starts at a low degree node in the network periphery and from their continues by "zooming out" from the periphery to the network core. Once within the network core the navigation proceeds to a hub, where a transition to the second "zoom in" phase occurs. In this second phase the navigation continues out of the network core to the final destination, again typically in the network periphery. The phases can be recognized by constantly decreasing distances to the destination node and increasing degrees of visited nodes in the "zoom out" phase followed by decreasing degrees in the "zoom in" phase after the transition in the network core occurs. In this part of our analysis we also try to identify similar pattern in user navigation click paths.

IV. Results

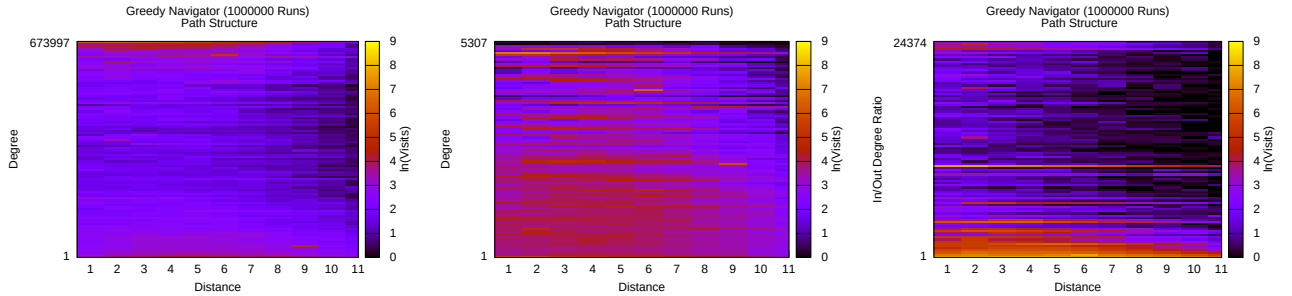
A. Structural Analysis

Wikipedia network clearly exhibits small-world properties (see Figure 1). The effective diameter of the network is slightly less than 6, which means that the huge majority of the nodes is reachable from each other in only a few clicks. The global network topology is dominated by a giant component, i.e. the largest strongly connected component includes more than 55% of nodes. This topology resembles the topology of the Web that is best described as the bow-tie model [32]. In this model, this strongly connected giant component occupies the network core and is connected to the IN component via back-links and to the OUT component via forward links. There are also direct connections between IN and OUT called TENDRILS. In an undirected case the weakly connected component contains all four elements SCC, IN, OUT, and TENDRILS. The size of the weakly connected component is around 99%. The



(a) Visited In-Degree Distribution (b) Visited Out-Degree Distribution (c) Visited In/Out Distribution

Fig. 4. Degree distributions of nodes visited during navigation. Some of the top nodes are visited frequently and represent navigation hubs. These nodes seem to be very important for navigation.



(a) Visits per in-degree/distance (b) Visits per out-degree/distance (c) Visits per degree-ratio/distance

Fig. 5. Density maps show the number of visits to nodes of a specific degree at a specific distance from the destination node. Color represents the number of visits with black/violet meaning less visits and orange/yellow representing more visits. The distance between nodes is calculated as the node distance in a node hierarchy as proposed in [30]. The Wikipedia hierarchy is constructed by the algorithm proposed in [31] which has been applied to the bipartite network of Wikipedia pages and categories they belong to. The density maps visualize the two phase navigational process – in the first "zoom out" phase users navigate from the periphery to the network core and in the second "zoom in" phase from the core to the final destination in the network periphery. The most frequent visits occur in the transition between phases (see orange/yellow regions in the top center region of the density map to the left, or orange/yellow line in the center of the density map to the right). These "transitional" nodes are the most important for the navigation process and are typically high degree nodes – navigational hubs. Navigation phases are not visible in the center Figure suggesting that out-degrees do not play that important role in the navigation process.

connectedness of Wikipedia is higher than that of the Web – on the Web all four components contain approximately one quarter of all nodes. Please note that our results are different than e.g. [33] as the size of the strongly connected component in that study was around 85%. The reason for these different results are different approaches to the Wikipedia network construction. In [33] the authors included also user, help, and talk pages into the network and this influences the network connectivity.

Clustering and Network Heterogeneity.

Degree distributions in Wikipedia network are heterogeneous and skewed (see Figure 2). In certain degree regions both in-degree distribution (k_{in}) and out-degree distribution (k_{out}) follow power-laws. Nevertheless, the existence of hubs and long tails in those distribution is clearly visible. Using the estimation method introduced in [34] we estimate the power-law exponent and the minimal degree of the power-law distributions. We obtain $\gamma = 2.28$ and $k_{min} = 1,668$ for in-degree distribution and $\gamma = 3.21$ and $k_{min} = 254$ for out-degree distribution. Please note that these results are comparable with other studies that estimated power-law exponents in Wikipedia networks, e.g. [33]. The $\frac{k_{in}}{k_{out}}$ exhibits also power-law behavior.

The average clustering coefficient of the Wikipedia network is around 0.33 which is very high. According to [19] a network with such combination of the values for clustering coefficient and power-law exponents is a navigable network.

B. Click Path Analysis

Distribution of Click Path Lengths.

The click path length distribution of successfully finished games is shown in Figure 3. A simple conclusion here is that whenever users are able to find the destination node they are typically extremely efficient in doing so. The average click path length is slightly higher than the effective diameter of the network – 6.27 as compared to 5.70 – meaning that on the average users need only a half click more than the global shortest path. Also, the shape of the click path distribution resembles the shape of the distribution of search path lengths in the original small-world paper by Milgram [12]. Both of these findings can be a strong indicator that user navigational strategies are similar to those strategies that humans apply for the search in their social networks.

Degree Distributions of Visited Nodes.

Now we turn to the analysis of the importance of the nodes of different degrees for the navigation process. For

that purpose we analyze the distributions of in-degree, out-degree and the ratio of in-degree and out-degree of nodes visited during navigation. All of the distributions show the existence of certain specific nodes, typically with high degrees or high degree ratio, which are visited in the large fraction of click paths. These nodes seem to be extremely important for navigation – they are navigational hubs (see Figure 4).

Navigation Patterns.

For in-degrees and in-degree/out-degree ratio we observe similar two phase navigational patterns as reported by [19] in our dataset. Thus, in the initial phase of their game users reduce the distance to the destination node by visiting nodes of increasing degrees, i.e. users enter the network core. In the network core transition to the second navigation phase occurs – users navigate to nodes in the periphery selecting the most similar nodes to the destination node. This phase is characterized by a decreasing distance to the destination and decreasing degrees of the visited nodes. We analyze this pattern by the density maps shown in Figure 5. Out-degrees seem less important for establishing navigational patterns.

This analysis also shows the importance of high degree nodes, as well as nodes with high degree ratio for the navigation. Typically, transition between two navigation phases occurs on such navigational hubs.

V. Conclusions

In this paper we presented the results of the initial analysis of user click paths in a Wikipedia navigational game. Our main contributions can be summarized as follows.

- Users are very efficient at navigation. They are able to find short paths between randomly selected pages.
- User navigation is a two phase process – in the first phase users "zoom out" to the network core and in the second phase they "zoom in" to their final destination.
- Certain high in-degree nodes and nodes with high "flow" ratio are very important for navigation. These nodes are visited very frequently – these are navigational hubs.

Abstract - Adoption of Web services delivered interoperability among different platforms. Nevertheless, a real contribution of service oriented systems is not only operability but powerful ways of inter and intra-corporative integration of autonomous IT systems. The most popular term, mentioned in this context, is - orchestration. Orchestration is a strongly supported mechanism which enables integration of component Web services into executable workflow processes. It uses XML based WS-BPEL language as a de-facto standard. This article inspects possible interaction patterns that are offered by WS-BPEL language and inspects different proposals for the development of WS-BPEL models. Most of them are based on model driven development where workflows are specified using languages with visual annotation or with higher level of abstraction which enable easier development or formal checking. Those models are afterwards automatically or semi-automatically translated into abstract and latter into executable WS-BPEL models.

I. INTRODUCTION

One of the main contributions of the SOA paradigm is an easy integration of diverse applications into processes that support long-running business transactions, workflow-based execution of business steps, error-handlings, compensation logic, messages transformations, protocol mediation and so forth. Integration is possible because of mechanisms that were developed accordingly with SOA paradigm and two the most popular are - orchestration and choreography. These mechanisms implement intra-corporative integration (*Enterprise Application Integration*, EAI) as well as inter-corporative integration (*Business to Business*, B2B).

Choreography is an integration mechanism that describes message sequences between different parties, and conditions and constraints under which messages are exchanged in an inter-organizational business process [1][2]. Choreography can be described from a global, and a local perspective. The global model of choreography specifies the message exchanges from an overall point of view [1]. The local choreography model defines the message interactions from the perspective of one party [1].

While choreographies serve as interaction contract between business partners, they are not meant to be executed by themselves [3]. Choreography model is described using XML-based WS-CDL language [2]. Since it is a global model of collaborations between all involved parties, each involved party can use it to build and test solutions that conform to this global model [2][3]. Choreography can be seen as a coordination mechanism between atomic Web services.

Orchestration is another integration mechanism which is very powerful and strongly supported by many vendors. Orchestration usually refers to an executable inter-organizational process that is provided by one party [1]. This executable process interacts both with external services of the other partners and with internal services. Language used for definition of orchestrations is WS-BPEL [4]. Orchestration models written in WS-BPEL are executable but they can also be abstract. Abstract processes serve a descriptive role [4]. Orchestration is usually seen as a mechanism for composition of atomic Web services. Since orchestration and choreography are closely tied up, there are approaches for deriving orchestrations from choreographies [1][5][6][3].

After a short introduction about main concepts related to SOA systems, let us inspect what the aim of this paper is and how it is organized. Section I gives an overview of high level perspective of reference architecture for SOA systems [7]. This high level perspective will give an answer where integration mechanisms are situated in the SOA architecture. Since standardization is tightly related to SOA, section II introduces SOA standard stack. Section III inspects main constructs of WS-BPEL language which is de-facto standard used for the development of orchestrations. This section concludes with the summary of patterns that can be modelled using WS-BPEL constructs. In section IV research areas related to orchestrations are identified. Those areas are challenging for a research since there are many unsolved or partially solved issues. Models for easier or formal development of orchestrations are presented in chapter V. Future work concludes the paper.

II. SOA REFERENCE ARCHITECTURE

In order to gain a better perspective of SOA, it is important to define its reference architecture. Reference architecture models the abstract architectural elements in the domain, independent of the technologies, protocols, and products that are used to implement the domain [8]. It can be defined at many levels of abstraction and for different purposes. High-level perspective of SOA reference architecture, proposed by the Open Group, and derived from the IBM, is described in [7]. It is used as a referent one in the paper because of its simplicity and its

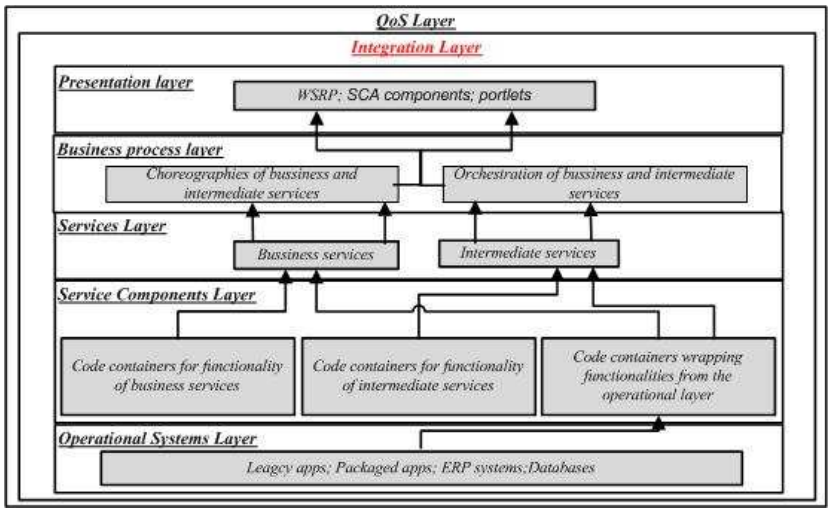

Figure 1. A High level perspective of SOA reference architecture

abstraction level. Fig. I describes a high level perspective of SOA reference architecture [7].

According to [7], SOA reference architecture is consisted of nine layers. The most important layers are the first five layers: *Operational Systems Layer*, *Service Components Layer*, *Services Layer*, *Business Processes Layer*, and *Consumers Layer*. They form a backbone of the SOA infrastructure. Every layer can be described in logical and physical aspect. Physical aspect describes how to implement each layer, whereas logical one describes building blocks of each layer in order to understand it. Following descriptions represent logical aspects of SOA layers.

Operational Systems Layer represents a collection of applications and data (programs and used databases) that already exist in the enterprise and can be potentially reused to implement functionalities of components in the *Service Components Layer* [7].

Service Components Layer is consisted of code containers that implement functionalities and maintain QoS of exposed services from *Services Layer* [9], and of wrappers that are used to expose functionalities of applications from the *Operational Systems Layer*.

Services Layer is consisted of exposed services, i.e. of abstract specifications of components from the *Service Components Layer*. These exposed services can be discovered, or can be statically bound and then invoked, or exploited as a part of composition systems [10]. Some service components from *Service Components Layer* may consume services from this layer in order to support integration [7]. These kinds of consumed services are *internal services* which are used to perform some intermediate functionality which will be delivered to certain service components (composite services). In this context, composite services are those ones that call other services, and they are transitively dependent of those services they call.

In today's business solutions, business processes play a central role in bridging the gap between business and IT. A business process captures the activities needed to accomplish a specific business goal [7]. *Business process layer* is consisted of business processes that are defined as compositions or coordination of services from the services layer.

Presentation layer is consisted of capabilities required to deliver functions of lower layers to end users or to other applications in application-to-application communication [7]. Although this layer is out of scope for discussions around SOA [10], it is advisable to use standardized ways when developing user interfaces. One of them, worth to be mentioned, is WSRP standard which offers a set of presentation-oriented Web service interfaces that allow the inclusion of and interaction with content from Web services [11].

In SOA reference architecture there are also vertical layers that intersect each of five, previously described, horizontal layers and those are *Integration* and *QoS Layer*. *Integration Layer* performs integration from *Operational Systems Layer* up to *Business Processes Layer*. Different adapter patterns can be used as mechanisms of integration from the operational systems layer into the service components layer [12]. Integration from service components layer into services layer is done using WSDL protocol which specifies binding, implying a location where services are provided [10]. Integration from *Service Components Layer* up to *Business Process Layer* is performed using mechanisms of *Enterprise Service Bus* (ESB). ESB, which has already been mentioned in the introduction, allows intelligent routing, long-running business transactions, protocol mediations, translating messages, running a large number of concurrent processes, etc.

QoS Layer has an aim to ensure that the service-level agreements (SLAs) and quality of services (*QoS*), expressed as a set of non-functional requirements of services like security, performance, availability, performance and scalability, are fulfilled successfully [12].

III. PROTOCOL STACK

Two previous chapters described main streamlines about SOA and Web services. This chapter inspects protocol stack of SOA infrastructure. It is important to

inspect all standard related issues because standardization is one of the main aspects of SOA.

It has already been stated that services form a backbone of SOA systems and that Web services are their most prevalent implementation. Set of protocols, that implements Web services, are WSDL [13], SOAP [14], and UDDI [15] - for description, communication, and discovery respectively.

WSDL is XML based and it is used to define public interfaces of Web services. Those interfaces describe messages being exchanged, operations, bindings, endpoints etc. Construct defined inside of WSDL are divided into abstract and concrete. Abstract definitions can be shared among many Web services. All those Web services are then of the same type.

Messages, exchanged between Web services and their clients, are contained within SOAP messages [14], and transported using traditional transport protocols, like HTTP. Entities involved in the process of communication are SOAP senders, SOAP receivers, and SOAP intermediaries who receive messages and forward them to their ultimate receivers. SOAP envelope holds business data while SOAP headers can be used to transport data related to addresses of ultimate receivers.

The third protocol, related to Web services, is UDDI protocol which represents public or private registries of Web services and programmatic interfaces for publishing, retrieving, and managing information about services described therein [15]. If there are multiple nodes of registries, they are replicated on a regular basis [16]. UDDI, WSDL, and SOAP form a basic package related to Web services.

Web services are not the only mechanism introduced with SOA. As already stated in the paper, there are mechanisms for development of composite applications (made of Web services) as well. When talking about Web services, a situation with standards is quite clear, but there is a lot of mess when talking about standards used for composition and coordination.

Choreography is a coordination mechanism that tracks message exchanges between Web services [17]. It describes global interactions and it is not executable. However, they can serve as blueprint for actual business process implementation for the different partners [3]. Protocols used for describing choreographies are WS-CDL [2] and WSCI [18]. A comparative analysis of two standards is given in [19].

Orchestration is a mechanism that refers to composition of Web services. It is executable and interacts with partner Web services [17]. De facto standard, used for specification and execution of orchestrations, is WS-BPEL [20] which suppressed vendor specific protocols XLANG and WSFL defined previously. BPMN [21] is a similar language for modelling of business processes, except that BPMN is not executable so its model must be translated into WS-BPEL [22] or implementation details must be added [23] in order to be executable. Modelling in WS-BPEL and BPMN languages is often made using graphical front ends which simplify this process and are more user-friendly to the business analyst [24].

TABLE I. A LIST OF WS-*SPECIFICATIONS AND THEIR RELATIONS TO WEB SERVICE STANDARDS AND WS-BPEL

	Web services	WSDL	SOAP	WS-Policy	WS-Coordination	WS-BPEL
WSDL	Describes		Binds to		Describes the service for	
SOAP	Enables communication between					
UDDI		Enables discovery of	Is accessed using			
WS-Security	Provides end-to-end security for		Uses	Uses		
WS-Policy	Governs		Uses			
WS-Transaction	Enables distributed transactions for				Provides protocols for	Provides protocols for
WS-RealiableMessaging	Improves reliability of		Provides guaranteed delivery for	Uses		
WS-Coordination	Manages context across		Uses			Manages context for
WS-BPEL	Orchestrates	Describes the service for	Uses			

There are also lots of WS-* specifications laying on top of Web service standards and providing a wide range of quality properties for the communications processes. Some of them are presented here. *WS-addressing* [25] provides a standard way of representing Web service endpoints in messages (known as *Endpoint References*), as well as numerous additional addressing characteristics. *WS-ReliableMassaging* framework [26] ensures guaranteed delivery of SOAP messages and a guarantee that messages are delivered in the order in which they are sent. When a group of Web services collectively interact to execute a unit of programming logic, it will often be required for these services to share a common context. *WS-Coordination* context management framework [27] provides a framework for context management. Web service contracts can be extended with policies that express additional constraints, requirements, and qualities that typically relate to the behaviours of services. *WS-policy* [28] is a language used for that purpose. *WS-AtomicTransaction* specification [29] enable cross-service transaction functionality comparable to the ACID-compliant transaction features found in most distributed application platforms. *WS-security* framework [30] provides fundamental characteristics of primitive security architecture for xml and web services, like: identification, authentication, authorization, integrity and confidentiality. *WS-Discovery* [31] defines a multicast discovery protocol to locate services. Relations between described specifications are described in the Table I [32].

IV. WEB SERVICE ORCHESTRATIONS

As already stated - mechanisms for the integration of standalone and loosely-coupled Web services were developed accordingly with SOA paradigm. Orchestration and choreography are the two most popular among those mechanisms. Orchestration is tightly related to WS-BPEL language and its constructs. Main concepts related to orchestrations have already been defined in the introduction of the paper. This paragraph defines main constructs of WS-BPEL language that is used to form a orchestration skeleton. Orchestration represents workflow execution of business steps and it is usually denoted as a business process. This process communicates with stand-alone Web services via partners. Partners provide Web services to the process, consume Web services from the process or interact in a two-way asynchronous conversation with the process. Every WS-BPEL process is itself a Web service described using WSDL. Using this idea as a foundation, more and more complex processes can be created out of lower level Web Service relationships.

Communication between process and its partners can be synchronous or asynchronous. Asynchronous communication is usually applied for long-lasting operations, while synchronous one for operations that return a result in a relatively short time [4]. The main construct that defines relationship between a partner and the process is a <*PartnerLinkType*>. A <*PartnerLinkType*> characterizes the conversational relationship between two services by defining the roles played by each of the services in the conversation and specifying the *portType* provided by each service to receive messages within the context of the conversation. Each role specifies exactly one WSDL *portType*. A <*partnerLinkType*> is defined inside of WSDL interfaces of partner Web services as an extension element using the WSDL 1.1 language extensibility feature. It can be placed into a separate WSDL document when the referenced *portTypes* are defined in two different services and then the WSDL import element (for importing the two different WSDL documents) must be used. Another scenario is to place them directly into the originating WSDL document and that is performed when the referenced *portTypes* exist in the same *targetNamespace*.

<*PartnerLinks*> are instances of *PartnerLinkTypes*. Within a *PartnerLink*, the role of the business process itself is indicated by the attribute *myRole* and the role of the partner is indicated by the attribute *partnerRole*.

PartnerLinks and *PartnerLinkTypes* are statically dependent on the abstract interface defined by *portTypes*, but not on the Ports which provide actual access information, including communication service endpoints and other additional implementation details. These implementation details can be dynamically discovered using endpoint references. An endpoint reference makes it possible in WS-BPEL to dynamically select a provider for a particular type of service. The WS-Addressing standard provides the schema for the *EndpointReference* type. Variables of this type can be assigned to a *PartnerLink* in order to modify the address and service information, thus providing the ability to modify the *PartnerLink* at runtime. Concrete semantics for doing this is specified in [33].

Variables are an important constructs used in WS-BPEL processes. They are used hold an incoming message from a partner, outgoing message to a partner, data required to hold the state of a process instance etc. WS-BPEL uses three kinds of variable declarations: WSDL message type, XML Schema type (simple or complex), and XML Schema element. WS-BPEL uses Xpath [34] as a query language to access variables. Variable updates occur through the <*assign*> activity.

During its lifetime, a business process instance typically holds one or more conversations with partners involved in its work. So WS-BPEL process needs to deliver messages not only to the correct destination port, but also to the correct instance of the business process that provides the port. When talking about instance routing, emphasis is to rely on the business data and communication protocol headers and to avoid implementation-specific tokens. <*correlationSet*> is a construct used for instance management. It holds a set of properties shared by all messages in the correlated group. The correlated group is a group of operations that use those correlating properties.

Process logic inside of WS-BPEL is expressed using activities divided into basic and structured activities. Basic activities perform elemental actions, while structured ones encode control-flow logic and therefore can contain other basic and/or structured activities recursively.

A list of basic activities is presented first. <*invoke*> activity is used to invoke an operation offered by a partner. Operations can be request-response or one-way

operations, corresponding to WSDL 1.1 operation definitions. Business process provides services to its partners through inbound message activities <*receive*>, <*pick*> and <*onEvent*> and corresponding <*reply*> activities. The <reply> activity is used to send a response to a request previously accepted through an inbound message activity such as the <*receive*> activity. <*receive*> waits for an invocation to arrive, while <receive> combined with <*reply*> are used to model asynchronous request-response interactions. <*receive*> activity plays a significant role in creating instances of the process. The only way to instantiate a business process in WS-BPEL is to annotate a <*receive*> activity (or a <*pick*> activity) with the *createInstanceattribute* set to "*yes*". The <*throw*> activity is used when a business process needs to signal an internal fault explicitly. The <*wait*> activity specifies a delay for a certain period of time or until a certain deadline is reached. The <*empty*> activity does nothing and can be used to provide a synchronization point. The <*exit*> activity is used to immediately end the business process instance. The <*rethrow*> activity is used in fault handlers to throw the fault they caught. A WS-BPEL process definition can include new activities, which are not defined by its formal specification, by placing them inside the <*extensionActivity*> element.

Structured activities prescribe the order in which a collection of activities is executed. The set of structured activities in WS-BPEL is not intended to be minimal. WS-BPEL structured activities can be divided into three categories: sequential control, concurrency and synchronization, and choice.

Important construct of WS-BPEL is a <*scope*>. A <*scope*> provides the context which influences the execution behaviour of its enclosed activities. A <*scope*> can declare elements that are visible only within the <*scope*>. A list of elements that can be declared in this way can be found in [4]. Every <*scope*> can have handlers that are associated to it. A list of available handlers is described below.

WS-BPEL processes leverage the concept of compensation. Compensation can be defined as a set of application-specific activities that attempt to reverse the effects of a previous activity that was carried out as part of a larger unit of work that is being abandoned. <*compensationHandler*> is a wrapper for an activity that performs compensation. <*compensate*> and <*compensateScope*> activities are used to invoke compensation handlers. Fault handling in WS-BPEL is something similar to compensation logic and it is designed to be treated as "reverse work," in that its aim is to undo the partial and unsuccessful work of a scope in which a fault has occurred. Compensation is not enabled for a scope that has had an associated fault handler invoked. Explicit <*faultHandler*>, attached to a scope provide a way to define a set of custom fault-handling activities, defined by <*catch*> and <*catchAll*> constructs. Termination handlers <*terminationHandler*> provide the ability for scopes to control the semantics of forced termination to some degree. Each scope, including the process scope, can have a set of event handlers <*eventHandlers*>. These event handlers can run concurrently and are invoked when the corresponding event occurs.

As it can be seen, WS-BPEL offers lots of constructs for modelling different kinds of business process elements. Summary of design patterns that can be modelled by previously explained WS-BPEL constructs are following: long-running business transactions, instance management, structured programming of processes (condition statements, loops, parallelism), event, fault and compensation handling, data manipulation, dynamic binding of partners (in conjunction with WS-Addressing), runtime-lookups for services (in conjunction with UDDI registries) or dedicated discovery services or WS-BPEL extensions [35].

V. RESAEARCH AREAS RELATED TO ORCHESTRATIONS

Although, some issues around orchestrations are quite standardized, there are still lots of orchestration fields that are not so standardized and are subject of intensive research. This chapter identifies categories of these research activities and presents some of them inside of each category.

A. Web Services Granularity Design Pattern

When developing atomic Web services, it is important to determine a right amount of functionality encapsulated inside of every one of them (level of granularity). Fine-grained services address small units of functionality or exchange small amounts of data, while coarse-grained services encapsulate larger chunks of capability, reducing the number of requests, necessary to accomplish a task, but on the downside, they might return excessive quantities of data, or it might be difficult to change them to meet new requirements [36]. There must be some well defined criterion that proposes what a well defined service is. According to [36], an important criterion is an adaptation to business processes. They say: "*the more a company can leverage a service for multiple processes, the more useful it is.*" One of the methods to determine services granularity is a functional decomposition [37]. Functional decomposition is a top-down approach and it is in contrast with the bottom-up one [38], even though their combination is often proposed [39]. Bottom up approach is usually used when there are existing systems that are going to be exposed as Web services.

B. Web Services Versioning Design Pattern

Web services versioning pattern includes all activities related to the versioning of public interfaces when changes occur inside of Web services. Web services are, just like any other software system, subject to permanent change. This software adaptation process is usually referred to as "software evolution", and is subject to a vital research community [40]. In order to perform versioning on server side, service registries need to store not only service versions but also service version graph which describes how they relate to each other [40]. Client side must use proxies which perform all communication with Web services and mentioned communication must be message based, not RPC based. Proxies should also perform selection over public registries and choose the

most appropriate version of Web services based on selection strategy [40]. This is just one approach and it is quite sure that contributions can be made to this design pattern part of SOA systems.

C. Legacy Systems Integration Pattern

There are lots of legacy systems offering well established functionalities. In order not to discard those systems, there are efforts trying to find the most optimal methods to exploit their functionalities and present them as services. It is important to determine what can be migrated from the original legacy system, and how the migration can be executed [41]. Generally, methodologies for integrating legacy systems in SOAs can be categorized into three classes: black-box reengineering techniques which integrate systems via adaptors, white-box reengineering techniques which require code analysis and modification to obtain the code components to be presented as Web Services, and grey-box techniques that combine black-box and white-box approaches [42].

Legacy systems possess functionalities that are valuable to the business. If there is no plan to discard them, it is important to find a methodology to integrate them into a new SOA system. Alternative to this integration is to write the same code using Web service technologies but from scratch which is very expensive and time consuming. Valuable contributions can be made to this design pattern.

D. Discovery mechanisms

There are several approaches for providing discovery functionality. Among them are Web service registries, Web service search engines, dedicated discovery Web services and other Web service discovery approaches [35]. UDDI supports mainly static Web services with long-term availability. Interaction with WS-BPEL processes is not provided.

Search engines provide also provide means for discovery but with similar limitations as registries.

Dedicated discovery is also a very popular approach. Specialized Web service performs discovery based on its internal mechanism [44]. That discovery service can be invoked by other services or by WS-BPEL process and can bind them to a search result using endpoint references (WS-Addressing).

According to [35], they have developed approach for service and device discovery as proposed by DPWS [45]. They developed special extensions for discovery to WS-BPEL. The approach is based on the Web service protocols *WS-Discovery*, *WS-MetadataExchange* and *WS-Transfer* which have to be provided by the WS-BPEL engine in order to support device and service discovery. For WS-BPEL engines that do not support mentioned additional standards, dedicated discovery services (performing the same logic) are introduced.

E. Communication patterns inside of orchestrations

According to [46] there are several types of communication systems offering cross-platform communication. They are categorized in the following manner: *remote procedure* and *object calls*, *message-queuing systems*, *shared data spaces*, and *publish/subscribe systems*. Publish/subscribe mechanism over extended time periods is extremely popular communication design pattern since *event-driven architecture* (EDA) [47] is tightly related to SOA. Generally publish/subscribe mechanism can be implemented in three different forms: *list-based*, *broadcast-based* and *content-based* [48].

In [49] publish/subscribe mechanism is enriched with interpreter services which are standalone services that intercept messages sent from their publishers and forward them to their subscribers at runtime [37]. All code that performs publishing, subscribing and interpreting is hidden inside of private logic of standalone Web services that offer public interfaces for publishing, subscribing and interpreting. Those standalone Web services can be orchestrated in a standard fashion using WS-BPEL.

Asynchronous Queuing is a variant of *message-queuing systems*. It establishes a central queue, where messages are put and from which messages are consumed, avoiding locking scenarios. *Synchronous Queuing* as opposed can be used for event-triggered communication [49].

The Intermediate Routing Pattern provides intelligent agent-based message routing [37]. Message paths can be dynamically determined using intermediary routing logic [50] which can be defined in the design time or computed during the runtime [51]. Routing logic is based on the content of message headers or on the content of message bodies and it can applied on SOAP or even on binary message formats [51].

According to [53], *message bus* pattern possesses uniform public interfaces and new services can be attached to it without any impact as long as they conform to those public interfaces. As opposed to *message bus* pattern, *message broker* pattern exposes different interfaces to the collaborating applications, and it can translate messages between these interfaces. In other words, the message broker does not enforce a common interface on the applications [54]. *Message bus*, as well as *broker pattern* should encapsulate certain mechanism inside themselves in order to know where to forward messages.

As it can be seen, there different design patterns and possibilities for their combinations and it is quite sure there is a lot of place for research in order to determine optimal design patterns and models for their development.

VI. MODEL DRIVEN DEVELOPMENT OF ORCHESTRATIONS

As it can be seen from the abstract, main focus of the paper is to present approaches of different models that are used for easier or formal development of WS-BPEL orchestrations. WS-BPEL is extremely complex XML based language. It is not intuitive and XML markup is extremely complex. Most developers are used to general purpose programming languages and WS-BPEL syntax is something new to them. Because of all these facts, there

are lots of efforts trying to develop models which ease the process of orchestrations development. This approach to development is known as a *model-driven development* (MDD) [56][57] in which orchestrations are specified using different models and afterwards translated into WS-BPEL code. Generally, models may be developed as a precursor to implementing the physical system, or they may be derived from an existing system or a system in development as an aid to understanding its behaviour [57]. Following analysis presents some approaches to model-driven development of orchestrations.

In [58] orchestrations are modelled using UML4SOA which represents UML extended with service specific model elements. Orchestrations modelled in UML4SOA are later converted into WS-BPEL and WSDL. In [58] there is an emphasis to introduce a minimal set of stereotypes for modelling SOA orchestrations making UML diagrams less complex. A first detailed mapping from UML to WS-BPEL is describes in [59], but according to [58] it introduces stereotypes for almost all BPEL 1.0 activities – even for those already supported in plain UML, which makes the diagrams hard to read. According to [58] other similar proposals for transformation from UML to WS-BPEL are presented in [60][61][62] but they lack extensions to model vital parts of orchestrations like compensation handling. Some proposals make UML diagrams extremely complex. Reference [63] represents model driven composition development ranging from abstract service definition, scheduling, construction, execution and evolution. Compositions are developed using *Basic Abstract Elements* and afterwards they are gathered into compositions using *Composition Rules*. Developed model is translated into WS-BPEL code in the final (execution) phase.

In reference [64] business processes are specified in computational independent models (CIM models) using BPMN notation and transformed into platform independent models (PIM models) also described using BPMN notation. Methodology presented in [64] includes parallel development of process performance indicators (PPIs) that serve for monitoring of orchestrations. Meta-models of PPIs are developed at CIM and PIM levels. PPI model at PIM level is merged with PIM orchestration model into platform specific model (PSM) which represents an orchestration model enriched with monitoring capabilities. PSM model is at the end translated into WS-BPEL executable code.

In [65] a lightweight variant of WS-BPEL language (*Blite)* is designated as well as Java engine *Blitec* which translates *Blite* code into WS-BPEL code deployable on the engine *ActiveBPEL* [66]. *Blitec* is defined as a language with a simpler syntax and a well-defined operational semantics. It only retains the core features of WS-BPEL. A complete *Blite* code is consisted of behavioural aspects of the orchestration and of a declarative part which contains implementation details. Lots of languages (that easy the development of orchestrations) try to retain the core features of WS-BPEL because WS-BPEL set of construct is not a minimal one [4], i.e. there are redundant constructs inside of it.

In [67] there is a proposal for transforming elements of BPMN into WS-BPEL elements. They also identify two problems that occur during transformation from BPMN into WS-BPEL. Firstly, BPMN diagram must be enriched with all implementation details before transformation into WS-BPEL. Secondly, badly constructed BPMN diagram can lead to invalid WS-BPEL code.

Choreography, as a mechanism, has already been introduced in the paper. There are approaches that perform derivation from choreographies into orchestrations. So, according to this approach, orchestrations can be developed upon choreographies [1][5][6][3].

There are approaches that focus on formal specification of Web service interactions because formal representation allows easier verification and detection of unexpected behaviours. Formal specification represents a specification of a system using a precise and unambiguous language. Unambiguous specifications are inherently testable, and impossible to interpret in more than one way [68]. Languages that fit into defined category are languages of process algebra, state charts and Petri nets. In [69] WS-CDL model with expressed time priorities is transformed into *prioritized-timed* Petri net model which allows a good perspective on dynamic behaviour of a system. In [70] π-like formalism is introduced and it allows generation of verified BPEL code and correction of existing BPEL specifications. Formal representation and associated logic allow a design time verification of the model behaviour and strengthen the correctness of service compositions. That is a reason why lots of research activities try to make contributions in this area.

There are many proposals for the development of models and rules of their transformation into executable WS-BPEL code. Lots of contributions can be made to this field. Firstly, it is necessary to identify subset of WS-BEL elements that is sufficient for development of all kind of scenarios inside of business processes. Secondly, a model for easier development of orchestrations must be specified as well as a transformation mechanism that must perform one to one mapping.

VII. CONCLUSION

This paper tried to define what orchestrations are and to introduce constructs of WS-BPEL language which is used for expressing orchestrations. Afterwards, main research areas, related to unsolved challenges in orchestrations, are introduced. Final part of the paper introduces approaches to model driven development of orchestrations. Different models and approaches are presented as a part of that paragraph. Future work is devoted to more detailed inspection of existing models used for easier and formal development of orchestrations and to transformation rules that map those models into final products – executable orchestrations. As an outcome of this work, a proposal for a proper model and transformation mechanism will be given. Considering identified research areas related to orchestrations, future work will also inspect current research of those areas in more detail and will give proper solution for each area: *Web services granularity determination*, *Web services versioning*, *discovery mechanism,* and *communication*

pattern design. As a completion of the work, a complete development methodology that integrates all previously mentioned proposals will be developed.

Superlinear speedup in OpenMP parallelization of a local PDE solver

G. Kosec*, M. Depolli*
*Institute Jozef Stefan / Department Communications systems, Ljubljana, Slovenia
gkosec@ijs.si, matjaz.depolli@ijs.si

This paper analyses the application of OpenMP parallelization on shared-memory systems, such as the increasingly available multicore systems. The parallelization of the local meshless numerical method is considered. The presented solution procedure is suitable for solving systems of coupled partial differential equations. The superlinear speedup is demonstrated on a solution of the fluid mechanics problem. Local core caches are identified as the source of superlinearity and a set of experiments is performed for the analysis of a cache induced superlinear speedup. For the experiments, a simple algorithm simulating the workload of the local meshless numerical method is used for the method complexity assessment.

I. INTRODUCTION

Computational time is an important factor in numerical simulations and it is often not addressed adequately. Parallel computers can compensate for the lack of single computer performance, but only in cases where an efficient parallelization method is known. Parallel algorithms for solving PDEs have been implemented on parallel computers for different applications [1, 2] The parallelization of a direct solver within the EFG method has been published in [3] with measured speedup and efficiency, which were 7.1 and 0.89, respectively, for four dual processors and systems with up to 2000 equations. Large sparse linear systems obtained by Free Mesh Method, which is a virtually meshless method based on FEM [4], have been parallelized on up to 64 processors [5]. Construction of the linear system was ideally parallelizable, while the parallel efficiency for solving the system was 0.6 on all available processors. Parallel RKPM in 3-D was implemented with efficiency of 0.6 on 64 processors [6]. The system of equations arising from 3-D meshless methods for crack propagations has been solved in parallel on 16 processors [7, 8]. The listed examples indicate that several demanding numerical applications need parallel implementations of meshless methods. Present paper tackles the OpenMP based parallelization of a local meshless solution procedure for fluid flow problems.

In this paper we focus on an intuitive and simple but still effective Local Radial Basis Function Collocation Method (LRBFCM) [9]. Besides local discretization scheme the local solution procedure for a pressure velocity coupling is considered. The local solution procedure is needed in order to achieve optimal parallel efficiency with minimal communication as the global approach requires complex parallelization code and a significant amount of interprocessor communication [10]. We demonstrate the efficiency of the OpenMP based local parallel implementation on the classical de Vahl Davis benchmark test. The results show superlinear regimes which are further investigated.

II. TEST CASES

A. Synthetic test case

For better insight into the performance of the OpenMP parallelization, a synthetic test (ST) with a single spatial loop within a temporal loop is designed. To control the calculation complexity a N_F floating point operations (FP) and data accesses are performed in spatial iteration. The size of data structure is also controlled by a D_S parameter. The computation structure of the synthetic case is similar to the natural convection case, but much simpler and thus more convenient for analysis. This simple test case is referred to in the following as ST.

B. Natural convection case

The classical De Vahl Davis [11] 2-D natural convection problem (NC) is considered for benchmarking purposes. The problem domain is a closed air-filled square-shaped cavity with differentially heated vertical walls with temperature difference ΔT and insulated horizontal walls. The non-permeable and no-slip velocity boundaries are assumed. There are several numerical solutions published in the literature [12-15] that make the test convenient for benchmarking purposes. The NC problem is described by three coupled PDE equations: mass (1), momentum (2) and energy conservation (3) equations, where all material properties are considered to be constant. The Boussinesq approximation (4) is used for the treatment of body force in the momentum equation. The natural convection is thus described by the following system of equations

$$\nabla \cdot \mathbf{v} = 0 \,, \tag{1}$$

$$\rho \frac{\partial \mathbf{v}}{\partial t} + \rho \nabla \cdot (\mathbf{v}\mathbf{v}) = -\nabla P + \nabla \cdot (\mu \nabla \mathbf{v}) + \mathbf{b} \,, \tag{2}$$

$$\rho \frac{\partial (c_p T)}{\partial t} + \rho \nabla \cdot (c_p T \mathbf{v}) = \nabla \cdot (\lambda \nabla T) \,, \tag{3}$$

$$\mathbf{b} = \rho [1 - \beta_T (T - T_{\mathrm{ref}})] \mathbf{g} \,, \tag{4}$$

with $\mathbf{v}, P, T, \lambda, c_p, \mathbf{g}, \rho, \beta_B, T_{\mathrm{ref}}, \mu$ and $\mathbf{b}$ standing for velocity, pressure, temperature, thermal conductivity, specific heat, gravitational acceleration, density, coefficient of thermal expansion, reference temperature for Boussinesq approximation, viscosity and body force,

respectively. The case is characterized by two dimensionless values

$$\mathrm{Ra}_T = \frac{|\mathbf{g}|\beta_T \Delta T \Omega_H^3 \rho^2 c_p}{\lambda \mu}, \quad (5)$$

$$\mathrm{Pr} = \frac{\mu c_p}{\lambda}, \quad (6)$$

referred as Rayleigh and Prandtl numbers. Ω_H stands for domain size.

III. MESHLESS NUMERICAL SOLUTION PROCEDURE

The introduced physical model does not have a closed form solution and in order to solve it, numerical approach has to be employed. In this paper we use a novel local meshless numerical method with local pressure velocity coupling. A general idea behind the local meshless methods is the use of local sub clusters of domain nodes, named local support domains, for the approximation of a field. With the selected support domain, an approximation function is introduced as a sum of weighted basis functions

$$\theta(\mathbf{p}) = \sum_{n=1}^{N_{Basis}} \alpha_n \Psi_n(\mathbf{p}), \quad (7)$$

where θ, N_{Basis}, α_n and Ψ_n stand for the approximation function, the number of basis functions, the approximation coefficients and the basis functions, respectively. The basis could be selected arbitrarily, however in this paper Hardy's Multiquadrics (MQs)

$$\Psi_n(\mathbf{p}) = \sqrt{(\mathbf{p} - \mathbf{p}^n)\cdot(\mathbf{p} - \mathbf{p}^n)/\sigma_C^2 + 1}, \quad (8)$$

with σ_C standing for the free shape parameter of the basis function, are used. By taking into account all support domain nodes and equation (7), the approximation system is obtained. In this paper we use collocation (the number of support nodes is the same as the number of basis functions). With the constructed collocation function an arbitrary spatial differential operation (L) can be applied on it

$$L\theta(\mathbf{p}) = \sum_{n=1}^{N_{Basis}} \alpha_n L\Psi_n(\mathbf{p}). \quad (9)$$

The implementation of the Dirichlet boundary condition is straightforward. In order to implement Neumann and Robin boundary conditions a special case of interpolation is needed. In these boundary nodes the function directional derivative instead of the function value is known and therefore the equation in the interpolation system changes to

$$\theta_{BC} = \sum_{n=1}^{N_{Basis}} \alpha_n \left(a \frac{\partial}{\partial \mathbf{n}} \Psi_n(\mathbf{p}) + b\Psi_n(\mathbf{p}) \right). \quad (10)$$

For the temporal discretization we use two-level explicit time stepping

$$\rho_0 \frac{\theta - \theta_0}{\Delta t} = \nabla\cdot(D_0 \nabla\theta_0) - \nabla\cdot(\rho_0 \mathbf{v}_0 \theta_0) + S_0, \quad (11)$$

where zero-indexed quantities stand for the values at the initial time, and D, S for general diffusion coefficient, and source term, respectively. The time step is denoted with Δt. Pressure-velocity coupling is performed through the correction of the intermediate velocity

$$\hat{\mathbf{v}} = \mathbf{v}_0 + \frac{\Delta t}{\rho}\left(-\nabla P_0 + \nabla\cdot(\mu\nabla\mathbf{v}_0) + \mathbf{b}_0 - \nabla\cdot(\rho\mathbf{v}_0\mathbf{v}_0)\right) \quad (12)$$

The equation (12) does not take into account the mass continuity and so corrections are added

$$\hat{\mathbf{v}}^{m+1} = \hat{\mathbf{v}}^m + \hat{\mathbf{v}}, \quad \hat{P}^{m+1} = \hat{P}^m + \hat{P}, \quad (13)$$

where m, $\hat{v}$ and $\hat{P}$ stand for pressure velocity iteration index, velocity correction and pressure correction, respectively. By combining the momentum and the mass continuity equations the pressure correction Poisson equation emerges

$$\nabla\hat{\mathbf{v}}^m = \frac{\Delta t}{\rho}\nabla^2\hat{P}. \quad (14)$$

Instead of solving the global Poisson equation exactly, the pressure correction is guessed from the divergence of the intermediate velocity.

$$\hat{P} = \ell^2 \frac{\rho}{\Delta t}\nabla\cdot\hat{\mathbf{v}}^m. \quad (15)$$

The proposed assumption makes solving of the pressure velocity coupling iteration local. Such an approach is very CPU efficient, as it needs only one computation for each pressure correction. With the computed pressure correction the pressure and the velocity can be corrected as

$$\hat{P}^{m+1} = \hat{P}^m + \zeta\hat{P}, \quad (16)$$

where ζ stands for the relaxation parameter. The iteration is performed until the criterion $\nabla\cdot\hat{\mathbf{v}} < \varepsilon_V$ is met in all computational nodes. The approach is similar to the artificial compressibility method (ACM), which has been recently under intense research [16-18] and in the framework of the Finite Differences Method to the SOLA approach [19]. However, the proposed approach retains the correct time transient which is not the case in SOLA and ACM approaches.

IV. IMPLEMENTATION AND SYSTEM ARCHITECTURE

The OpenMP (Open Multi-Processing) is an Application Programming Interface (API) that supports

multi-platform shared-memory multiprocessing programming in C, C++, and Fortran, on most processor architectures and operating systems, including Unix, Mac OS, Microsoft Windows and others. The OpenMP consists of a set of compiler directives, library routines, and environment variables that influence run-time behavior. In the OpenMP implementation the master thread forks off a specified number of slave threads and divides the task among them. The threads run concurrently on the shared data, with the runtime environment allocating threads to the available processors. Each section of the code that is designed to run in parallel is marked with a preprocessor directive. After the execution of the parallelized code, the slave threads join back into the master thread, and the program executes serially from there on. The OpenMP can implement the task parallelism and the data parallelism at the same time. It runs particularly effective on multicore computer architectures based on the multilevel memory hierarchy and fast shared-memory caches. For the purpose of the present analysis we use *#pragma omp parallel for* directive with static scheduling. The implementation of ST case is schematically represented in Figure 1 and of NC in Figure 2.

We run our natural convection tests on a computer system with four Intel Xeon E7450 processors, each with six cores, system clock of 2.40 GHz, 1066 MHz front side bus (FSB), and 64 GB of shared main memory. The system has three levels of cache hierarchy: each core has 32 kB of L1 instruction cache and 32 kB of L1 data cache. Typical L1 latency is 2 clock cycles. Each pair of cores shares 3 MB of L2 cache, for a total of 9 MB of shared L2 cache per processor. Typical L2 latency in the case of L2 cache hit is 6 clock cycles. Each processor has 12 MB of shared L3 cache. Typical L3 latency in the case of L3 cache hit is 60 cycles or 120 clock cycles in the case of L3 cache miss and main memory hit.

In addition, we create a preliminary cache miss analysis for the ST case on a computer system with two quad-core Intel Xeon 5520 2.26 GHz processors, 1066 MHz FSB, and 24 GB of shared main memory. Each core has 32 kB L1 instruction cache, 32 kB L1 data cache, and 256 kB of L2 cache. Each CPU has 8 Mb of L3 cache that is shared among its four cores. Cache latencies are 4 clock cycles for L1 data cache, 10 cycles for L2 cache, and 40 cycles for L3 cache.

V. RESULTS

The results of numerical integration for the NC case have been already explored in details in our previous work [20]. The presented solution procedure has been also successfully applied on several other thermo-fluid problems, where the latest and also the most complex simulation was solidification of a binary alloy [21]. Since the numerical methodology has been already assessed in the past we will focus only on the parallel efficiency in the present paper. The performance is evaluated through the speedup defined as

$$S = \frac{t_1}{t_{Nc}}, \tag{17}$$

With t_1 and N_C standing for the computational time and the number of cores. In Figure 3 the cavity streamlines and temperature contours together with the speedup for $Ra=10^8$ are presented. The fluid flow computations show superlinear speedup when working with high number of discretization nodes (N_D). As expected with increasing number of cores the superlinear effect is lost. To explain the range of superlinear regime we use ST case with controllable complexity. We focus on computations with one and two cores ($N_C = \{1, 2\}$). In this preliminary demonstration we use only one floating point operation and one data transfer per iteration. Besides the computational time we measure the L2 and L3 cache hit rates defined as

$$H_{1,2}^{L2,L3} = \frac{number\ of\ hits}{number\ of\ all\ accesess}, \tag{18}$$

where subscript defines the number of cores the computation was performed on, and superscript the considered cache level. The CPU performance counters that record cache hit and miss events were accessed via Intel Performance Counter Monitor [22]. In Figure 4 the computational time and speedup with respect to N_D for $N_C = \{1, 2\}$ is presented together with cache hit rate measurements. It is clearly visible that superlinear speedup occurs when the L2 cache hit rate starts to decline on the single core while it stays at nearly 100% on two cores. In this regime, increasing N_D causes the working set to become too large for the single core L2 cache while it still fits into two L2 caches. The single-threaded program slows down in a comparison to the two-threaded program as the result of the increased number of accesses to L3 cache. Roughly after $N_D = 8000$ the working set becomes too large even for both L2 caches, therefore L3 cache must be accesses for most of the data operations regardless of the number of threads. From that point on the speedup can no longer be superlinear on the account of accumulating L2 caches. We identify similar behavior with accumulating L3 caches, of course at much higher values of N_D as the L3 caches are considerably larger than L2 caches. The effect is presented in Figure 5.

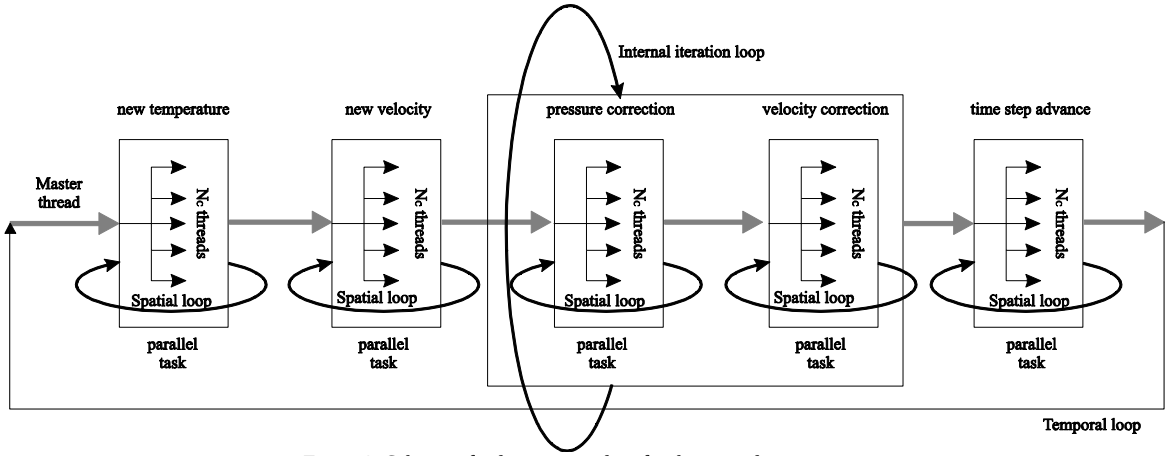

Figure 2: Scheme of solution procedure for the natural convection case.

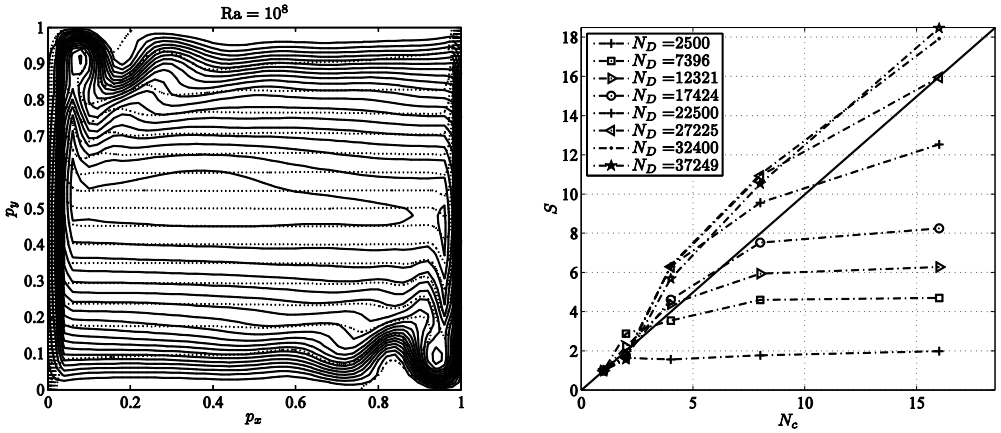

Figure 3: Cavity streamlines and temperature contours for Ra=10^8 (left) and speedup with respect to N_D and N_C (right).

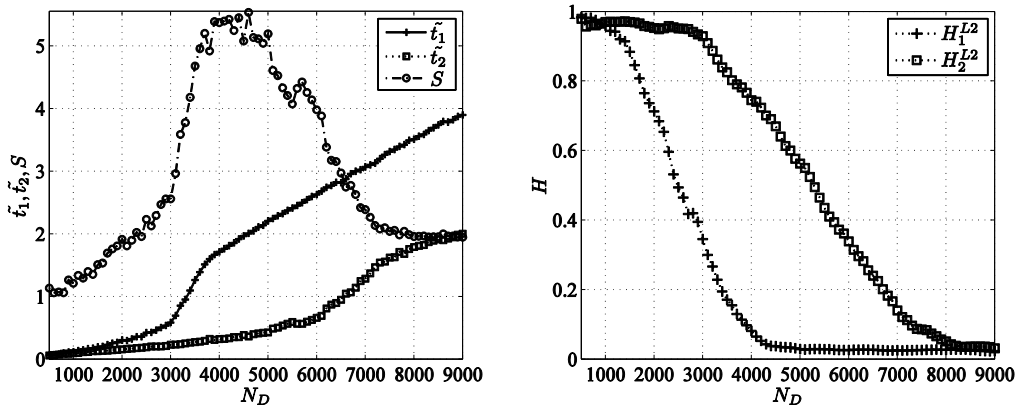

Figure 4: Dimensionless computational time and speedup with respect to N_D (left) and cache hit rate measurements (right) in regime where superlinear speedup occurs due to the accumulating L2 caches.

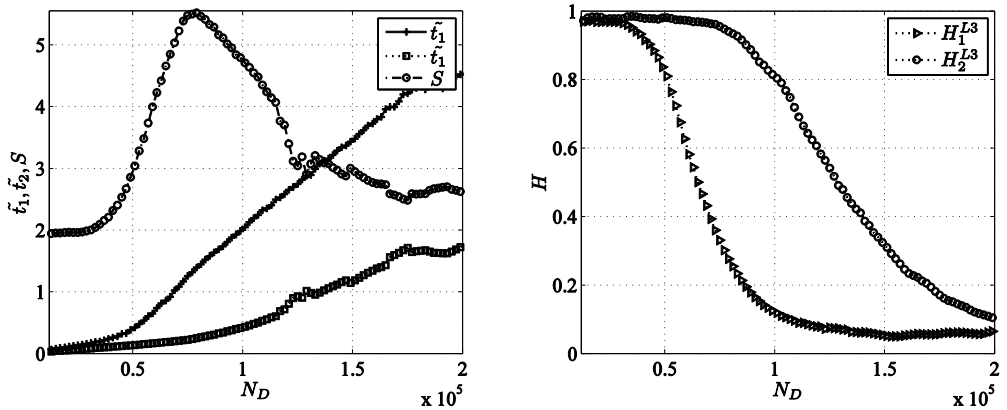

Figure 5: Dimensionless computational time and speedup with respect to N_D (left) and cache hit rate measurements (right) in regime where superlinear speedup occurs due to the accumulating L3 caches.

Note that dimensionless computational times are used as the absolute values do not supply any additional information, yet the dimensionless values are more convenient for presentation. Speedup values are not scaled in any way.

VI. CONLUSION

In presented paper the OpenMP based parallel implementation of local meshless solution procedure for solving fluid flow problems is demonstrated. In the speedup analysis the superlinear regimes are identified. Through the analysis of simpler computational problem the background of superlinearity is explained. The accumulating caches at different levels govern the extremely high speedups in certain regimes. Presented analysis is of a preliminary nature and it lacks quantitative assessment. Our future work will be focused in a more detailed analysis of the cache behavior in the realistic and more complex situations.

***Abstract*—The process of software-as-a-service (SaaS) development is critical in developing time as well as in quality aspects. The tools for semiautomatic or even automatic composition of software services are already implemented. However the problem of the quality of the resulting SaaS system still exists. There is huge number of the services-components (subsystems) with the same functionality but different non-functional attributes and relatively short time to evaluate them. In this paper the method for optimal set of services-components selection taking into account non-functional properties of services-components is proposed. This method can be used as an extension of other proofs-as-programs methods and service-oriented software development systems. We have presented the simulated annealing algorithm with variable neighborhood search for automated software composition and have evaluated this algorithm experimentally, comparing it to the Classic SA and Greedy algorithms. The algorithm for the evaluation and improvement of the services-components set we are proposed in this paper presents the class of algorithms because it is possible to change the globality of our optimization algorithm using different values of the parameters.**

I. Introduction

Contemporary software development process is affected by the paradigm shift towards software services and Cloud computing [1]. Each complex *software-as-a-service* (SaaS) solution can be composed using software components (atomic services other compound SaaS solutions). Several tools (e.g. [2], [3]), which can perform this composition in semi-automatic or even automatic way are already implemented [4], [5], [6].

However the process of contemporary software development is still critical in the aspects of developing time and quality. One of the problems is the huge quantity of the components with the same functionality but different non-functional attributes [7] and relatively short time to evaluation of such attributes.

To solve the problem of the fast evaluation and improvement of the component-based system we are offering to use stochastic methods. The main goal of this paper is to present stochastic method for the evaluation of the component set to improve the resulting quality of component-based software.

The paper is organized as following. Section 2 outlines the composition problem. Section 3 describes deductive software composition method which is used as a base for our software composition method. Section 4 presents the simulated annealing method, adopted to solve this problem. Section 5 exposes the experiment of the implementation of proposed method and its results. Section 6 surveys related work. Finally, conclusions are made and future work is discussed.

II. Compositional problem

We are investigating the problem of fast composition with the resulting component-based system with the higher values of the non-functional properties as possible. In our approach the concept *software component* is defined as the software artifact which provide atomic or compound service. Each component is expressed as a tuple:

$$C = \langle PRT_{out}, PRT_{in}, \Delta, \Omega_C \rangle , \tag{1}$$

where PRT_{out} is the set of the output ports, PRT_{in} – the set of the input ports, Δ – the set of the constraints, Ω_C – the set of the credentials of the component.

The port is general concept for the communication between components. Each required interface, event sink or static property can be considered as the input port and each provided interface, event source or static property can be considered as the input port. The sets of the input and output ports are defined as the unions:

$$PRT_{in} = \Im_{in} \cup E_{in} \cup S; PRT_{out} = \Im_{out} \cup E_{out} \cup S, \tag{2}$$

where $\Im_{out}$ and $\Im_{in}$ are the sets of provided and required interfaces, E_{out} – the set of event generating by the component, E_{in} – the set of the component's event sinks. S is the set of properties of component. Properties are used to change configuration of particular component.

The credentials Ω_C of the component C in this model are used to express non-functional properties. Each Ω_C is constituted from particular credentials ω_i:

$$\Omega_C = \omega_1, \omega_2, \ldots, \omega_n, \quad 0 \leq \omega_i \leq 1, \tag{3}$$

The concept of constraints Δ can be used to express the semantics of component using preconditions, postconditions and invariants. In order to simplify our approach we do not take in the account the semantics of components. We just assume that all components in the set of candidates have been selected regarding these constraints already.

The component-based SaaS system in this model is defined using the couple of non-empty lists:

$$CSys = \langle CS, CN \rangle, \tag{4}$$

where $CS = C_1, C_2, \ldots, C_m$ is the list of the components, CN – the glue-code abstraction. Glue-code abstraction can be considered in two different ways: as a wrapper and as a script. In this paper the wrapper-like implementation of the glue-code abstraction have been chosen. In this case CN_i is defined as a set of the connections:

$$cnn_{i,j} = \langle P_{in}, P_{out}, CType \rangle, \quad cnn_{i,j} \in CN_i, \tag{5}$$

where each connection is defined by the connection's type $CType$, and by the couple of the ports P_{in}, P_{out}.

In this paper we are analyzing particular situation when $CSys$ and its constituents is already known (e.g. Fig. 1), i.e. the complete list of the components included in the $CSys$ system and list of connections CN are already given.

III. Deductive methods for software composition

Deductive synthesis of programs (or *proofs-as-programs* method) is the class of methods for software synthesis introduced in early 1980's [8], [9]. This method has been successfully used in several systems (e.g. CoCoViLa) [10]). The main idea of *proofs-as-programs* method is that programs can be constructed taking into account only their structural properties, i.e. input/output variables. Each preprogrammed module is supplied with an axiom stating under which condition it can be applied, and what values it computes. The axiom doesn't disclose details of module's implementation. The structure of program is synthesized, and the full program is built from preprogrammed modules [10]. This method was generalized by Poernomo group [11].

Proofs-as-programs deals with the black-box entities. Software services and components in general are black-box entities also so *proofs-as-programs* method was adopted to componet-based and service-based paradigms. The SoCoSyS software synthesis system was created as an implementation of *proofs-as-programs* method [12], [6]. The system is able to find components (SaaS subsystems) and give the connection schema. Because of (*proofs-as-programs*) method this solution is *a priori* correct and there is no need of comprehensive testing. However at the solution search time SoCoSyS don't takes into account the non-functional requirements for the system and non-functional properties of the components.

As a case-study we have intention to extended our component-oriented software development system SoCoSyS and add to it additional optimization module. The result of SoCoSyS includes only first set of components, which can be composed to the specified software system. But this set can be (and often is) not optimal by the terms of non-functional properties of resulting system. To complete the solution we are developing the optimization module which must to find best possible set of components in the relatively short time.

In this paper we suppose that $CSys$ is the result of early mentioned deductive software synthesis method implemented in the SoCoSyS system. Let's suppose that initial set of components T is large enough and each component C_i in the system $CSys$ can be changed by at least one another component C_j.

IV. The Algorithm for Optimal Component Set Search

As is mentioned before we want to achieve as much good software quality (in terms of non-functional properties) of $CSys$ system as it is possible in very short time (comparing to time required for global optimization). For this reason the complete evaluation of all possible combinations of components is not used. Instead of this we are using the Simulated Annealing method [13], adopted by us to solve compositional software development problem.

The algorithm for the evaluation and improvement of the component set we are proposed in this paper is very flexible. We are able to change the globality (i.e. possibility of global optimum detection) of our optimization algorithm using different values of parameters α, β, T and g.

A. Prerequisites

Let us assume that component based system is constituted from m components $C_1, C_2, \ldots, C_m$, and each of them can be selected from the set

$$A_i = a_1^i, a_2^i, \ldots, a_{M_i}^i, 1 \leq i \leq m$$

where i is the index of particular component we want to change, M_i – the number of components in the set A_i. Let us denote X the set of all possible combinations

$$X = \otimes_{i=1}^{m} A_i,$$

and one of the possible resulting set of components:

$$x = (x_1, x_2, \ldots, x_m), x \in X.$$

To evaluate the quality of each set of components x in terms of non-functional requirements, let's denote the quality function

$$f(x) = \sum_i \sum_j x_i.\omega_j \cdot s_j, \tag{6}$$

where s_j is a weight (or an impact factor) of j-th credential. The usage of the weights gives to software architect possibility to specify which particular credentials are most important. We are assuming that bigger values of the credentials of the components will give the higher quality of the resulting software also. Consequently, we will use this quality function as the goal function to be maximized:

$$f(x) \to max. \tag{7}$$

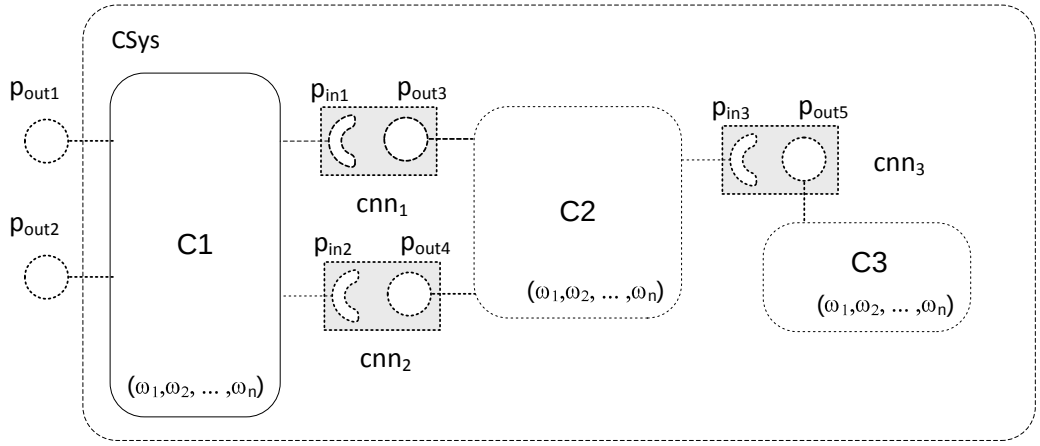

Fig. 1. Example of component-based system composed from three components.

Let us also denote the similarity matrix

$$R^i = \left[R^i_{s,u}\right]_1^{M_i} \tag{8}$$

where $R^i_{s,u}$ defines the similarity of the components a^i_s and a^i_u. Note that $0 \leq R^i_{s,u} \leq 1$. The similarity matrix is needed to evaluate which components in the set is *closer* each other (subsec. IV-B, Step 2). In order to make the decision time as much short as it is possible, this similarity matrix is created before the start of the compositional problem solving process. This matrix can be constructed/updated in the time of uploading component to repository. The element of similarity matrix can be computed by using many different formulas. In our approach we are using the following formula:

$$R^i_{s,u} = 1 - \frac{\sum_{j=1}^{n} \left|a^i_s.\omega_j - a^i_u.\omega_j\right|}{n}, \tag{9}$$

where n is the number of the credentials of the components.

B. Algorithm

We are using the Simulated Annealing algorithm adopted to solve compositional problem. We are using also the contribution of previous work [14], namely the variable neighborhood search technique in the Step 2 of the algorithm. However this technique is adopted to our compositional problem, new terms of "similarity" and "neighborhood" in the set of the components have been defined. Our algorithm is as follows:

Step 1 Let us assume that initial component set is x_0, the list of initial components' indexes is $v = (v_1, \ldots, v_m)$, the quality of the component-based software system is $f_0 = f(x_0)$, the temperature is T_0, the number of already performed iterations $k = 0$ and particular values of the coefficients α_0, β_0 and g_0 are selected.

Step 2 The list of indexes $r = (r_1, r_2, \ldots, r_m)$ is generated. Each value of r_i is selected such as

$$\frac{\sum_{l=1}^{r_i-1}(R^i_{v_i,l})^{\alpha_k}}{\sum_{l=1}^{M_i}(R^i_{v_i,l})^{\alpha_k}} < \eta_i \leq \frac{\sum_{l=1}^{r_i}(R^i_{v_i,l})^{\alpha_k}}{\sum_{l=1}^{M_i}(R^i_{v_i,l})^{\alpha_k}}, \tag{10}$$

where η_i is uniform distributed in the unit interval, v_i is the number of the variant of previous step for i-th component, $1 \leq v_i \leq M_i, 1 \leq r_i \leq M_i, 1 \leq i \leq m$. The candidates to the r_i are iteratively chosen from the range $(1, \ldots, M_i)$ until the inequality (10) is true. η_i remains the same for each candidate to the r_i, but for each new i new value of the η_i is generated.

Step 3 New set of similar components $y_{k+1} = (y^1_{k+1}, y^2_{k+1}, \ldots, y^m_{k+1})$ is taken, where $y^i_{k+1} = t^i_{r_i}, \forall i \in (1..m)$ and new list of components' indexes is fixed: $v = r$.

Step 4 The value of the function $f_{k+1} = f(y_{k+1})$ is calculated and the values of T_{k+1} and α_{k+1} recalculated as follows: $T_{k+1} = g_k \cdot T_k, \alpha_{k+1} = \beta_k \cdot \alpha_k$, where $0 < g_k < 1, \beta_k > 1$. The parameter g_k is classical parameter of the Simulated Annealing method [13]. It is used to change *the annealing temperature* T_k. The coefficients α and β are the part of our variable neighborhood search algorithm and are used in the Step 2. α is used to calculate probability that credentials of neighborhood component are better than current component. If α is constant the choice of different component can be granted after large number of iterations, even the best candidate was already known. To avoid so dynamic "jumps" the value of α is constantly changed by coefficient β. α

Step 5 If

$$e^{\frac{f_{k+1}-f_k}{T_{k+1}}} > \mu, \tag{11}$$

where μ is uniform distributed in the unit interval, then $x_{k+1} = y_{k+1}$ (i.e. new selected set of components is approved as the possible solution), else $x_{k+1} = x_k$ (i.e. new selected set of components is rejected), $k = k + 1$ and go to Step 2.

Step 6 The algorithm stops when fixed number of iterations is already performed or the criteria have not improved after several steps.

V. EXPERIMENT

Composition method can be evaluated using testbed problems (e.g. [4]) and real-life problems (e.g. [5]). As an example for the experiments we have used composition problem of the relatively small component-based software system $CSys$ which must give flight and hotel booking information. As was designed in the conceptual model, this system consist only 10 components: $C_1, C_1, \ldots, C_{10}$ (e.g. flight time calculation service, the hotel availability check service). The number (M_i) of components-candidates for each component is 10 for all i (e.g. services from Lithuanian portals fly.lt, tiesiai.lt, greitai.lt). Each component in the i-th set of candidates is equivalent to component C_i according functional requirements, but non-functional credentials of each component are different. We have chosen 10 as the number of different credentials (n) for each component (e.g. security level, average response time).

The number of iterations required to calculate global maximum of the function (6) is too big and the decision (which components exactly should be composed in $CSys$) should be given faster.

The goal of our experiment – to evaluate the efficiency of proposed simulated annealing and variable neighborhood search algorithm for automated software composition in the small number of iterations. We have solved the same compositional problem with the same sets of components using 5 different algorithms (Fig. 2):

1) Global optimization with the complete evaluation of each possible set of components-candidates(1000 iterations).
2) Greedy algorithm.
3) Clasic_SA: Classic simulated annealing algorithm with the following values of the parameters: $T = 50$, $g = 0.8$. Because Clasic_SA do not use variable neighborhood search, the values of α and β have been set to 1.
4) Our_SA_01: Our simulated annealing and variable neighborhood search algorithm (Our_SA_01) with the following values of the parameters: $T = 50, g = 0.8, \alpha = 2, \beta = 0.85$. The value of $\alpha > 1$ is chosen to decrease the probability to chose next candidate component x_{r_i} with very low similarity to current component x_{v_i}. The value of $\beta < 1$ have been chosen to minimize the impact of α when the number of iterations is increasing. This preserves the algorithm from probability of the repeated evaluation of the same candidates.
5) Our_SA_02: Our simulated annealing and variable neighborhood search algorithm with the following values of the parameters: $T = 50, g = 0.8, \alpha = 0.5, \beta = 1$. The values of α and β have been chosen different from the Our_SA_01 to evaluate the scope of the possibilities of proposed algorithm.

The results of the experiment are exposed in Fig. 2, where X axis shows the number of iterations and Y axis shows the value of quality function. The results have shown that purposed algorithm is able to find approximately best solution in relatively short time. After the small number of iterations (100 and 200) our algorithm with the different values of the parameters have shown better results comparing to classic SA and to Greedy algorithms. The proposed algorithm (especially Our_SA_02 modification) show best results after 600 and more iterations also. We are observing a little descends of the result values in particular cases (e.g. after 400-500 iterations). It is necessary to investigate particular impact of the values of coefficients on the overall performance of the algorithm.

VI. RELATED WORK

The problem of the evaluation of the software components is on the focus of several computer science research groups. However most of the papers are taking into account different aspects of this problem comparing to our approach.

The work of M.C.Jaeger, G.Muhl and S.Golze [15] surveys six component selections algorithms. However their approach does not cover the simulated annealing algorithm. Moreover the point of view to the composition problem is different. In the paper [15] the software composition problem is considered as a problem of Knapsack or Resource constrained project scheduling. In contrast to it we suppose that the number of recourses (i.e. SaaS components) for the composition is not constrained because we are focused on the development-time process, not on run-time process.

The research of the S.Bouktif group is based on stochastic methods, including the genetic algorithms [16] and simulated annealing [17]. As in our paper they are focused on the software quality too. However it is easy to see dividing line between this and our approaches. The main focus of the S.Bouktif group is on the process of the software quality evaluation in the early stage, i.e. the evaluation of the trust of the software credentials, given by the experts. In our approach we do not examine the origins of the credentials Ω. Instead of this we are solving the problem of maximization of the summary value credentials of the resulting software system.

Our approach is done using relatively simple quality function. However in particular cases the change of the values of component's credentials can affect the behavior and credential values of other components in the system. Because of the black-box nature of the software components it is difficult to evaluate dependences between input and output components. The idea of the form of this function is considered e.g. in the [18] paper. Our approach can be refined by changing the quality function (6).

VII. CONCLUSIONS AND FUTURE WORK

1) We have proposed the method for optimal component set selection taking into account non-functional properties of components. This method have been used in the extended SOCOSYS system and can be used as an extension of other *proofs-as-programs* methods and component-based software development systems.
2) We have presented the simulated annealing algorithm with variable neighborhood search for automated software composition and have evaluated this algorithm experimentally. The results of comparison of our SA&VS

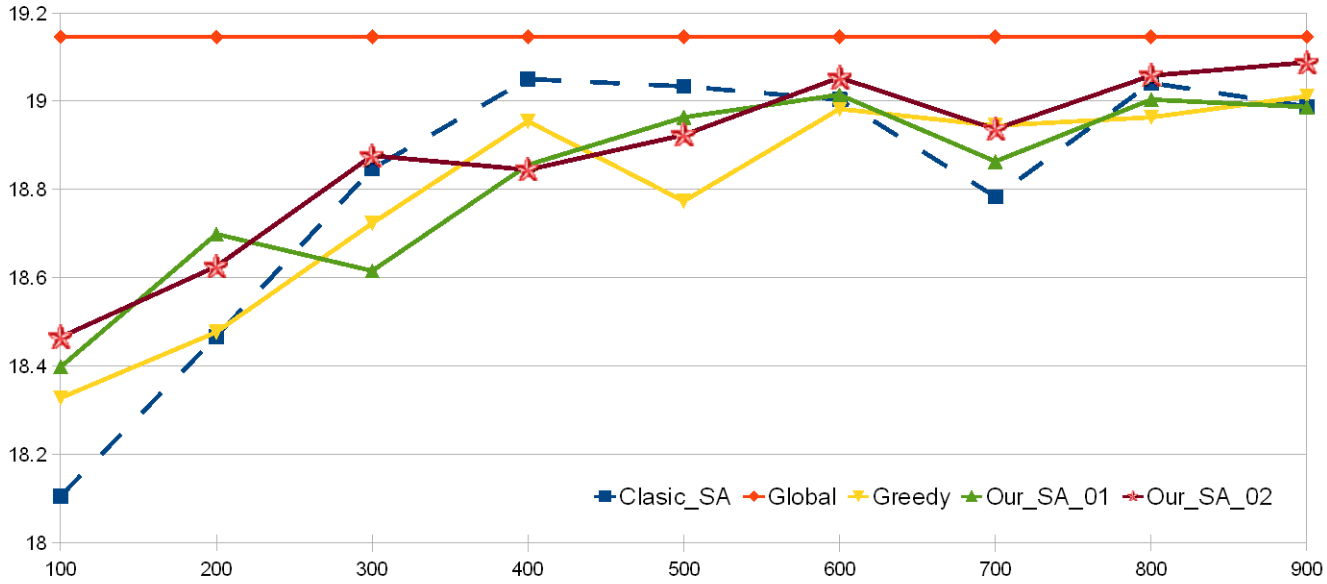

Fig. 2. The results of the evaluation of the algorithms.

algorithm with the Classic SA, and Greedy algorithms showed that created algorithm is able to approximate to best know solution in relatively short time.

3) In fact the algorithm for the evaluation and improvement of the component set we are proposed in this paper presents the class of algorithms because it is possible to change the globality (i.e. possibility of global optimum detection) of our optimization algorithm using different values of parameters α, β, T and g. Our future research plans is the complete investigation of the impact of the values of parameters α, β and the form of the quality function to the efficiency of the algorithm.

Running High Performance Linpack on CPUGPU clusters

Draško Tomić*, Dario Ogrizović**
*Hewlett-Packard Croatia, Zagreb, Croatia
** Center for advanced computing and modeling / Faculty of Maritime Studies, Rijeka, Croatia

Abstract – A trend is developing in High-Performance Computing with cluster nodes built of general purpose CPUs and GPU accelerators. The common name of these systems is CPUGPU clusters. High Performance Linpack (HPL) benchmarking of High Performance Clusters consisting of nodes with both CPUs and GPUs is still a challenging task and deserves a high attention. In order to make HPL on such clusters more efficient, a multi-layered programming model consisting of at least Message Passing Interface (MPI), Multiprocessing (MP) and Streams Programming (Streams) needs to be utilized. Besides multi-layered programming model, it is crucial to deploy a right load-balancing scheme if someone wants to run HPL efficiently on CPUGPU systems. That means, besides the highest possible utilization rate, both fast and slow processors needs to receive appropriate portion of load, in order to avoid faster resources waiting on slower to finish their jobs. Moreover, in HPC clusters on Cloud, one has to take into account not only computing nodes of different processing power, but also a communication links of different speed between nodes as well. For this reasons we propose a load balancing method based on a semidefinite optimization. We hope that this method, coupled with a multi-layered programming, can perform a HPL benchmark on CPUGPU clusters and HPC Cloud systems more efficiently than methods used today.

I. INTRODUCTION

With the advent of GPU cards, HPC landscape has changed dramatically. More FLOPS/watt are available, less space for HPC equipment is needed, and supercomputing on every workstation becomes possible. In addition, GPU concept brought better performance/cost ratio, faster communication within CPUGPU nodes, and smaller footprint, i.e. dense computing. Besides pros, there are several cons when using GPU accelerators on HPC clusters. Some of them are non-uniform programming models, a need for deployment of advanced cooling systems, e.g. water-cooling, and a fact that many HPC applications are still not supporting GPU accelerators. At least but not the last, HPL benchmark has proven not to be so efficient on heterogeneous clusters like on CPU only clusters. As of today, HPL is a standard benchmark for Supercomputing, and a performance measure for ranking supercomputers in the TOP500 list of the world's fastest computers [1].

The package tries to find a solution of the system of N linear equations with N unknowns. In fact, this is a common engineering task, in matrix notation expressed as:

$$Ax = b \tag{1}$$

Where x is a vector of N unknowns, A is a matrix of N x N cofactors in the system, and b is a vector of N values that upper equation needs to satisfy.
HPL uses Gaussian elimination with partial pivoting as a method of finding a solution for (1). The process of Gaussian elimination has two parts. The first part (Forward Elimination) reduces a given system to triangular form. The second step uses back substitution to find the solution of the system above. In the case of Gaussian elimination with partial pivoting, the algorithm requires pivot element not be zero. Interchanging rows or columns in the case of a zero pivot element is necessary. Choosing pivot element with large absolute value improves the numerical stability. The number of millions of floating point operations per second (MFLOPS) performed with this method is:

$$MFLOPS = 2/3 \cdot N^3 + 2 \cdot N^2 + O(N) \tag{2}$$

HPL runs for different matrix sizes N searching for the size N_{max} that delivers the maximal performance R_{max}. The benchmark also reports the problem size $N_{1/2}$ where the system reaches $R_{max}/2$, i.e. the half of its performance. An excellent paper is [2], covering all the details and variants of overview of HPL benchmark .

II. PERFORMANCE MODELLING OF HPL ON CPUGPU CLUSTERS

An Effectiveness Factor (EF) of a certain computer system is a ratio between maximal computation power achieved and computation power installed. A well-designed computer system will have EF near 1, while low EF values are signs for problems coming from architectural, application or both domains. Observing in this way, HPL is the application for measuring EF.

In fact, one can sum installed MFLOPS computational power in a certain HPC system, and then run HPL to see how much MFLOPS this system can actually deliver. Speaking in a top500 jargon, *Rpeak* is computation power high-performance cluster can theoretically deliver, while *Rmax* is a maximum number of MFLOPS achieved during a HPL benchmarking run. A quick comparison of clusters on top500 list without GPU accelerators with those having GPU accelerators shows that EF is remarkably lower on CPUGPU clusters, and that EF does not scale well with overall number of nodes in cluster. Therefore, when designing CPUGPU clusters, it is of the outmost importance to predict their HPL performance with a high level of accuracy. Thus, we need some benchmarking results from smaller clusters, and then a right approach to scale HPL on much larger clusters, even those that will take place on top500 list in forthcoming years. For example, benchmarking results of HPL done on 16- node cluster [3] can serve as a starting point for the performance prediction of larger cluster, if right extrapolation method is applied. In this benchmarking case, each computing node was HP Proliant DL360 G7 with two 5670 Intel 2.67 GHz six-core processors and 48GB of RAM, with RHEL as operating system, and OpenMPI, CUDA and Intel compiler running on each node. From the manufacturer data sheets Tesla NVIDIA 2050 can deliver at its peak 1030 Gflops of floating point arithmetic with double precision, while two Intel 5670 six-core processors on HP Proliant DL360 motherboard are theoretically able to deliver 140 Gflops of the same type of arithmetic. Therefore, a sum of these two values provides Rpeak of 1170 GFLOPS for a single computing node. HPL runs on a various cluster sizes ranging from 1 to 16 delivered following Rmax and EF values:

Nr. nodes	Rmax	Rpeak	EF
1	640	1170	0.55
2	1319	2340	0.56
4	2551	4680	0.55
6	3814	7020	0.54
8	5092	9360	0.54
10	6295	11700	0.54
12	7498	14040	0.54
14	8771	16380	0.53
16	10050	18720	0.53

Table 1: HPL benchmarking results on uniform CPUGPU cluster

Results show us that scaling of HPL in this cluster is good with very few percents of EF decrease starting from a single node to the maximum cluster size. However, EF values in overall are disappointing, although cluster nodes are equal.

III. HOW TO PERFORM EFFICIENT HPL ON HETEROGENEOUS CPUGPU CLUSTERS

In case cluster nodes are not of equal processing power, we are speaking about heterogeneous CPUGPU clusters. There are very few published results about HPL benchmarks in heterogeneous CPUGPU clusters, not only because such clusters are still rare [4]. The main problem found in heterogeneous clusters is still present today. The shining example of this problem is Map Reduce algorithm and its implementations, for example Hadoop. The problem is if one node is slower than the rest of cluster nodes, it can slow down the entire cluster. However, a team of researchers working on Tsubame 1.0 [5] delivered a good work in this area. They were able to report a HPL result with 53% efficiency on the overall Tsubame 1.0 cluster. Load balancing strategy chosen for their HPL implementation on Tsubame 1.0 was fair scheduling. That is, allocation of each parallel task to CPUGPU cluster node was according to its weight. That means, the more instructions a certain process has to execute, a faster resource will handle it. Taking into the consideration that this cluster was a mix of AMD, Intel and various GPU processors, and comparing it with HPL efficiency of the 16-node uniform cluster already discussed before, not so bad result at all.

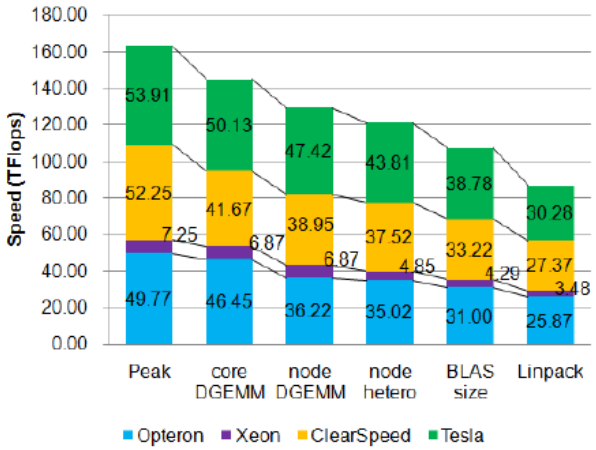

Figure 1: HPL performance on Tsubame 1.0 with 10480 Opteron cores, 640 Xeon cores, 624 NVIDIA and 648 Clearspeed GPUs

The main reason for a relative low EF in both clusters considered before is the core design of HPL, designated for homogeneous clusters. HPL is two-step process. First step is LU factorization of the dense matrix *A* with partial pivoting. Next step is the solution of the resulting triangular system of equations. Let us restate that overall workload of HPL benchmark is $(2/3)N^3 + 2N^2 + O(N)$. LU factorization takes almost all the computation time of the benchmark. Matrix update and the upper (U) matrix factorization dominate the computation time of the LU factorization. Matrix update is a DGEMM (Double Precision General Matrix Multiply) form of the matrix-matrix multiply, and it takes $O(N^3)$ operations.

On the other side, solver kernel takes $O(N^2)$ operations, because of *right*-hand-sides (DTRSM) kernel. Therefore, if one wants to further accelerate HPL on heterogeneous CPUGPU clusters, both load balancing of HPL processes tasks between computing nodes and within computing nodes has to be done. For uniform CPUGPU clusters, it is easy to balance HPL processes between nodes: each node should receive the same portion of load via MPI. Load balancing within nodes requires more attention, because CPU and GPU resources within nodes are not of the same processing power. A good strategy is to put more load on GPU resources, and less load on CPU resources, in a way that both resources finish their jobs at the same time. OpenMP, the Open Source implementation of MP, is a good choice to accomplish this. At last, one needs to program portions of HPL routines within CPUs and GPUs, normally via compilers (CPU) and Streams (GPU). It is clear from the before considerations that effective HPL on CPUGPU clusters requires at least two things: Adequate load balancing and multi-layered programming, i.e. MPI, MP and Streams programming. A team running HPL benchmarking of TianHe-1 [6] has performed a good work involving adequate load balancing of processes and multi-layered programming.

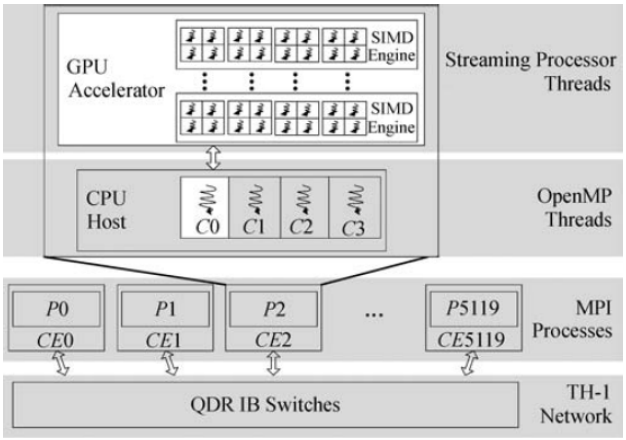

Figure 2: Multi-layered programming model of HPL implementation for the TianHe-1.

The final Linpack result was Rpeak of 563 TFLOPS, which compared to Rmax of TianHe-1 delivers EF of 0.701, considerably more than Tsubame 1.0 and 16-node Proliant cluster.

IV. CLOUD IS CHALLENGING US

While the phenomena of the relatively slow node (compared to the rest of cluster members) able to freeze the whole cluster can be solved in traditional HPC clusters by fair load balancing (each node receives a load proportional to its performance), this is not a right approach when doing HPC on Cloud.

CPUGPU computing nodes in Cloud may have not only various performances, but also communication links between them can have various bandwidth. Only one slow link is able to slow down the entire cluster. Therefore, a challenge of running HPL efficiently is much bigger than on heterogeneous CPUGPU clusters. The main question here is how to distribute load on computational nodes in a balanced way (nodes receive a load with respect to their processing power and utilization) while at the same time minimizing communication times between nodes. Following an idea first described in [7], and with the advent of the algorithm described in [8], a load-balancing algorithm relying of the semidefinite optimization of the data-flow matrix with respect to the second largest eigenvalue in magnitude (SLEM) was developed [9]. This approach is not limited to HPC clusters only, as for example shown in [10]. However, there is no currently known semidefinite optimization with respect to SLEM, which works on general and non-symmetric matrices. Therefore, if one wants to deploy a semidefinite optimization of the certain matrix with respect to the SLEM, he needs to transform it to its doubly stochastic and symmetric form. Because this transformation takes a considerable amount of time, a method is still not appropriate for general cloud applications. In contrary, many HPC workloads, like HPL, tend to execute in a huge number of equal iterations, and it is feasible to consider semidefinite optimization as a first choice in such a cases. We can rewrite this load-balancing problem as:

$$Minimize\ \ \mu(P) \tag{3}$$

With respect to:

$$P \geq 0,\ P1 = 1,\ P = P^T \tag{4}$$

Where P is doubly stochastic and symmetric matrix, its transpose is P^T, $\mu(P)$ is SLEM, and 1 is unary vector.
In a heterogeneous CPUGPU and Cloud based HPC clusters consisting of many computing nodes with different processing power, each node can have many multi-core processors, cores can have different working frequencies and utilizations, and computing nodes can communicate with other nodes via interconnection communication links of various bandwidths. Let us denote the total number of processing nodes with *n* and a total number of cores within a certain node with m. Additionally, let us denote a frequency and utilization of the core j within node i with ps_{ij} and u_{ij} respectively. Thus, we can express the effective processing speed of node *i* as:

$$eps_i = \sum_{j=1}^{m} \frac{ps_{ij}}{u_{ij}} \tag{6}$$

Additionally, we can denote with bw_{ij} a bandwidth of the communication link between processing nodes *i* and *j*. Then the following matrix can describe effective processing speed of computing nodes and bandwidth of communication links between them:

$$Y = \begin{bmatrix} eps_1 & bw_{12} & . & bw_{1n} \\ bw_{21} & eps_2 & . & bw_{2n} \\ . & , & . & . \\ bw_{n1} & . & bw_{n,n-1} & eps_n \end{bmatrix} \quad (7)$$

Because optimization algorithm is limited to symmetric matrices only, one needs to transform matrix *Y* to its symmetric form. In general, communication links are bidirectional and not of equal bandwidths in both directions. Therefore, we can write symmetric form of matrix *Y* as:

$$Y_s = \begin{bmatrix} eps_1 & \min(bw_{12}, bw_{21}) & . & \min(bw_{1n}, bw_{n1}) \\ \min(bw_{21}, bw_{12}) & eps_2 & . & \min(bw_{2n}, bw_{n2}) \\ . & , & . & . \\ \min(bw_{n1}, bw_{1n}) & . & \min(bw_{n,n-1}, bw_{n-1,n}) & eps_n \end{bmatrix} \quad (8)$$

If one wants to describe the data-flow within a certain HPC cluster, then besides Y_s, he needs to describe algorithm running within this cluster as well. One of way to do this is to construct weighted and vertex labeled directed graph, with edge weights representing number of messages computing nodes have to exchange with each other, and vertex labels representing number of operations computing nodes have to perform. From this graph, one can construct accompanying matrix *A*, with main diagonal elements representing number of operations computing nodes have to perform, and of-the-main-diagonal elements representing number of messages computing nodes have to exchange with each other.

$$A = \begin{bmatrix} a_{11} & a_{12} & . & a_{1n} \\ a_{21} & a_{22} & . & a_{2n} \\ . & . & . & . \\ a_{n1} & a_{n2} & . & a_{nn} \end{bmatrix} \quad (9)$$

Usually there are many algorithms executing on HPC cluster. Then, for each algorithm matrix *A* needs to be constructed and sum of these matrices will represent all algorithms. The next step is to express a data-flow within HPC system. One of way to do this is to perform Hadamard multiplication between matrices Y_s and A:

$$P_n = \begin{bmatrix} eps_1 \cdot a_{11} & \min(bw_{12}, bw_{21}) \cdot a_{12} & . & \min(bw_{1n}, bw_{n1}) . a_{1n} \\ \min(bw_{21}, bw_{12}) \cdot a_{21} & eps_2 \cdot a_{22} & . & \min(bw_{2n}, bw_{n2}) \cdot a_{2n} \\ . & . & . & . \\ \min(bw_{n1}, bw_{1n}) \cdot a_{n1} & \min(bw_{n2}, bw_{2n}) \cdot a_{n2} & . & eps_n \cdot a_{nn} \end{bmatrix} \quad (10)$$

Matrix P_n is symmetric; however, it is not doubly stochastic. In order to perform semidefinite optimization of P_n with respect to SLEM, one needs to convert it to its doubly stochastic form. A following recursive equation (11) developed in [9] transforms P_n to its doubly stochastic form. Experimental results in [9] show that by doing the following recursion in not more than 100 iterations, an absolute error is less than 0.1%.

$$P_{n+1} = (D_n)^{-1/2} P_n (D_n)^{-1/2} \quad ; n = 1,...,\infty \quad (11)$$

Where:

$$D_n = \begin{bmatrix} d_1 & 0 & 0 & 0 \\ 0 & d_2 & 0 & 0 \\ 0 & 0 & . & 0 \\ 0 & 0 & 0 & d_n \end{bmatrix} \quad (12)$$

Where each element on the main diagonal D_n is a sum of the corresponding row of the P_n:

$$d_i = \sum_{j=1}^{n} P_{ij} \quad ; \; i = 1,...,n \quad (13)$$

After optimization, one needs to obtain the deterministic form of matrix P_n. Let us denote with Q_n optimized version of the matrix P_n. It can be shown that the following transformation can perform this:

$$Q_{n-1} = (D_n)^{1/2} Q_n (D_n)^{1/2} \quad ; n = \infty,...,1 \quad (14)$$

Again, the number of iterations needs to be limited. Experimental results in [9] show that within 100 iterations error drops below 0.1%. At the end of the recursive process in (14), Q matrix will contain an optimal data-flow for a given cloud. In order to obtain an optimal workload distribution on the processing nodes, one has to convert an optimal data-flow in the number of operations computing nodes have to perform. One way to do this is to use trace of the matrix, which gives the sum of the matrix main-diagonal elements. The optimal workload distribution A_o will be then:

$$A_0 = \frac{trace(A)}{trace(Q)} Q \quad (1) \quad (15)$$

This method has been experimentally [9] proven to be effective in a HPC clusters consisting of several dozens of heterogeneous computing nodes.

We hope to continue with experiments when HPC Cloud systems with CPUGPU nodes will be more available to academic community: at this time, we are not aware of any HPC Cloud system with CPUGPU nodes of various performances.

V. CONCLUSION

HPL benchmark is a standard tool for the performance measurement of HPC systems. Applied to homogeneous and heterogeneous CPUGPU clusters, it still shows significantly smaller EF values then on CPU only clusters. There are several reasons for it. The most important is that initial design of HPL was for large SMP and CPU only clusters. Not of the less importance, HPL was born in times when the cloud was meteorological object only, not IT term. Therefore, it is also not suitable for the performance measurement of HPC Cloud systems. We are now at the crossroad and have to choose a right direction: One is leading towards the significant modification of HPL, in order to give it new functionalities needed for the better performance measurement of the heterogeneous and Cloud HPC systems. Another is to rethink the existence of HPL and start searching for new, more appropriate HPC benchmarks. On both roads, there is clear evidence for better, i.e. multi-layered programming habits, and for more effective and wiser load balancing strategies.

The Segmentation of Data Set Area Method in the Clustering of Uncertain Data

I. Lukić, M. Köhler, N. Slavek
Faculty of Electrical Engineering, Department of Computer and Software Engineering
Kneza Trpimira 2b, 31000 Osijek, Croatia
lukic@etfos.hr

Abstract - The **clustering of uncertain objects is a well researched field. This paper is concerned with the clustering of uncertain objects with 2D location uncertainties, due to object movements. The location of a moving object is reported periodically, thus the location is uncertain and is described using a probability density function. Data on moving objects and their locations is placed in distributed databases. The number of objects in a database can be large, thus their proper clustering is a challenging task. A survey of existing clustering methods is given in this paper and a new clustering method is proposed. This method is called Segmentation of Data Set Area. Using this method the execution time of clustering objects is shortened, compared to previous methods. In this method, the data set area is divided into sixteen segments. Each segment is observed separately and only the clusters and objects in a given segment and its neighbouring segments are observed. Experiments were conducted to evaluate the effectiveness of the new method. These experiments proved that this method outperformed previous methods by up to 28% in computing time whilst using the same memory space.**

I. INTRODUCTION

In many databases, the data contains uncertainties, and mining useful data from such uncertain databases is not a simple task. Different factors, such as measurement errors, sampling discrepancies and outdated data sources can contribute to the data uncertainty. Various methods are used to cluster data with location uncertainty, such as UK-means, MinMax pruning and Voronoi pruning. Clustered objects are mutually similar, near to the cluster centre and similar objects are kept in the same group. The location of moving objects is uncertain, because object locations are reported periodically. Thus, an object's exact location must be estimated using the last known location and the uncertainty value. The uncertainty is determined by the location measurement error, the speed of the moving object, the last reported direction and the time elapsed. Clustering methods are used for the tracking of moving objects, such as mobile devices, traffic services etc.

Uncertain object location is not represented as a discrete point, but as an uncertainty region. In practice, an uncertainty region is represented by a probability density function (PDF). In this paper, the object's location is presented in 2D space, with a two-dimensional uncertainty. In real life applications, the PDF can be specified using a Gaussian distribution, with its means and variances [1]. For Gaussian distributions, the density function is exponentially dropped, meaning the probability density outside of a certain region is zero. Thus, each object can be bounded by a finite bounding region. This region is limited by the maximum speed of the object and the elapsed screening time. The main issue in the clustering process is the execution time, because efficiency is extremely important in real time applications. Most of the computational time is lost on expected distance (ED) calculations. A large number of sample points is used to represent each PDF, and numerical integration is applied to calculate the expected distance. In [2] some pruning methods are introduced, to avoid ED calculations. With pruning methods, the objects are represented as bounding regions. Using these pruning methods, some clusters are eliminated as candidate clusters if a closer cluster for an observed object is found. Thus, computation of the expected distance from the object to the pruned clusters is avoided. In [3], pruning methods based on Voronoi diagrams are introduced. In this pruning method, the spatial relationship among the cluster representatives is taken into consideration. Voronoi pruning is an improvement on the basic bounding region method. In this paper, a new clustering method is presented to improve the clustering process. This new method is called Segmentation of Data Set Area (SDSA). In this method, the data set area is divided into sixteen segments. Each segment is observed separately and only the clusters and objects in a given segment and its neighbouring segments are observed. Thus, the number of objects and clusters under observation is decreased. New investments are not needed, because this method can be implemented within all the aforementioned methods.

II. COMPARISON OF EXISTING METHODS

An object's location can exhibit uncertainty in two different aspects: as existential uncertainty and as value uncertainty. An object is existentially uncertain when there are doubts as to the object's existence [15]. In a relational database, the object is associated with a probability value that indicates the confidence of its presence [4]. Efficient query evaluation on probabilistic databases is well explained in [5]. Value uncertainty appears when the object is known to exist, but its value is uncertain and its location is not precise. An object is modelled as a minimum bounding region (MBR), which bounds all possible location values. In [1], MBR is described as the probability density function. The clustering of objects with value uncertainty, such as location uncertainty, is studied in this paper. Cluster

analysis is used to identify the most probable values of the model parameters [7], such as the means of Gaussian mixtures, to identify high-density connected regions [8], such as areas with high population density, or to minimise the total squared distance to the cluster centres [9]. In this paper the last case is studied. The distance can be measured as city-block distance, Minkowski distance [10], Euclidian distance etc. An object's location is represented by the probability density function, which is represented by a set of sample values. To improve accuracy a large number of samples is needed. The distance must be calculated for all samples, thus the computational cost is higher than with simple distance calculation [11]. In the basic clustering algorithm, UK-means [11], the expected distance (ED) is calculated from all objects to all clusters. As stated earlier, ED calculations are expensive, thus the UK-means algorithm is ineffective. In [2], the MinMax pruning method is presented. It is more effective than the UK-means, because many ED calculations are avoided. Another method for uncertain data clustering is presented in [13]. In this method, Voronoi diagrams and R-trees are used for cluster pruning, making it more effective than MinMax pruning.

The SDSA method, presented in this paper, is used for the segmentation of a data set area and it can be combined with any of the above cluster pruning methods. Through the synthesis of these methods, the execution time is reduced compared to original methods.

A. UK-means

The K-means algorithm is used for clustering objects with certain locations. For the clustering of uncertain objects K-means was modified, which resulted in the UK-means [1] method. In this method, m points are selected as cluster representatives. Each object o_i is assigned to a cluster cj, whose representative cluster point has the smallest expected distance ED(o_i, c_j) to the object o_i. After all objects are assigned to clusters, the cluster representative points are recomputed as the mean of all objects assigned to the cluster c_j. These steps are repeated until a solution converges. The expected distance is calculated for each object cluster pair. The expected distance calculation requires numerically integrating the function weighted by the corresponding probability density function. The PDF is represented by a large number of sample points, and the computational costs are very high. To improve the performance of UK-means, different algorithms are developed. Their intention is to reduce the time spent on ED calculations. In the following chapters, a few of them are presented. The UK-means algorithm is shown in Figure 1.

Choose k arbitrary points as c_j ($j = 1, \ldots, k$)
repeat
  for all $o_i \in O$ **do** /*assign objects to clusters*/
    for all $c_j \in C$ **do**
      Compute ED(o_i,c_j).
    $h(i) \leftarrow j^*$ where j^* minimises ED(o_i,c_j)
    (among $c_j \in C$)
  for all $j = 1, \ldots, k$ **do**
    $c_j \leftarrow$ centroid of $\{ o_i \in O \mid h(i) = j \}$
until C and h become stable

Figure 1. The UK-means algorithm

B. MinMax pruning

The MinMax pruning method [2] is an improvement on UK-means. First off, the terms used are defined.

Definition 1: Uncertain objects are collections of data O= $\{o_1,\ldots,o_n\}$ in m dimensional space R^m, where the distance between two objects is:

$$d(o_i, c_j) \geq 0 \quad (1)$$

Definition 2: The probability density function of each object at each point x ε R^m is $f_i(x) > 0$ x ε R^m, where for all points inside MBR:

$$\int_{x \in R^m} f_i(x)dx = 1 \quad (2)$$

Definition 3: The expected distance from an object o_i to any point y is calculated using this formula:

$$ED(o_i, y) = \int_{x \in A_i} d(x,y) \cdot f_i(x)dx \quad (3)$$

A_i is a finite region and $f_i(x)=0$ is outside the region A_i.

Definition 4: The goal of clustering is to find a set of cluster points C=$\{c_1,\ldots,c_m\}$ and relations h:$\{1,\ldots,n\} \rightarrow \{1,\ldots,m\}$, in which the total expected distance from the objects to the cluster

$$TED = \sum_{i=1}^{n} ED(o_i, c_{h(i)}) \quad (4)$$

is minimised.

In the MinMax pruning method the minimum bounding rectangle MBRi is used to avoid unnecessary expected distance calculations. MBR is the smallest rectangle that is equal to the finite region A_i as shown in Figure 2.

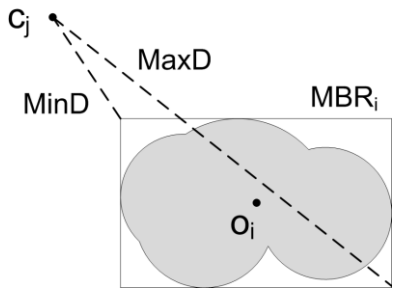

Figure 2. MBR of object, MinD and MaxD distance from object to cluster

Using MBR and inexpensive Euclidian distance calculations, some clusters are pruned as candidates for an object. Thus the expected distances from those clusters to the object are not computed. For each object, the minimum distance to a cluster is defined:

$$MinD(o_i, c_j) = min_{x \varepsilon MBRi} d(x, c_j) \quad (5)$$

The maximum distance to a cluster:

$$MaxD(o_i, c_j) = max_{x \varepsilon MBRi} d(x, c_j) \quad (6)$$

The smallest distance among all of the maximum distances:

$$Min\ MaxD(o_i, c_j)=min_{cj\varepsilon C}\{\ MaxD(o_i, c_j)\} \quad (7)$$

It is obvious that the minimum distance from an object to a cluster is less than the expected distance, and the maximum distance is higher than the expected distance from an object to a cluster, as shown in the following formula:

$$MinD(o_i, c_j) \le ED(o_i, c_j) \le MaxD(o_i, c_j) \quad (8)$$

Then, if it is satisfied:

$$MinD(o_i, c_p) \ge MaxD(o_i, c_j) \quad (9)$$

Without computing the expected distance, the cluster c_p is pruned from the object o_i, and the execution time is shortened. MinMax pruning is shown in Figure 3.

for all $c_j \in C$ **and objects** $o_i \in O$ **do**
  Compute MinD (o_i, c_j) and MaxD (o_i, c_j)
  Compute MinMaxD (o_i)
for all $c_j \in C$ **do**
  if MinD (o_i, c_j) > MinMaxD (o_i)
  then Remove c_j from CC_i
for all remaining clusters calculate ED

Figure 3. The MinMax pruning algorithm

C. Voronoi pruning

In the Voronoi pruning method, differing from MinMax pruning, the geometric structure of R^m is observed, meaning the spatial relationships between clusters are considered. In [3], it is shown that Voronoi pruning is theoretically sounder than MinMax pruning. The same authors presented hybrid methods for even more efficient pruning. Using a set of clusters $C=\{c_1,...,c_m\}$, space R^m is divided into m cells with the following property:

$$d(x, c_p) \le d(x, c_q) \quad \forall\ x\varepsilon V(c_p),\ c_p \ne c_q \quad (10)$$

After constructing the Voronoi diagram, the next step in iteration is Voronoi cell pruning, where it is checked if the MBR_1 of an object o_i is completely inside the Voronoi cell $V(c_j)$. If it is, the object o_i is assigned to a cluster c_j, and there is no need for ED computation, because all other clusters are pruned. In Figure 4 it is shown that the MBR_2 of an object o_2 is completely inside the Voronoi cell V_3, thus the object o_2 is assigned to a cluster c_3. However, if the MBR_1 is partially outside the Voronoi cell V_3 the object o_1 cannot be assigned to a cluster c_3. For all objects which are not assigned to any of the clusters, the expected distance must be calculated. Voronoi pruning can be combined to develop hybrid methods, such as the combination of Voronoi and Bisector pruning, the cluster shift method etc. The Voronoi pruning method in combination with the Bisector pruning method is shown in Figure 5.

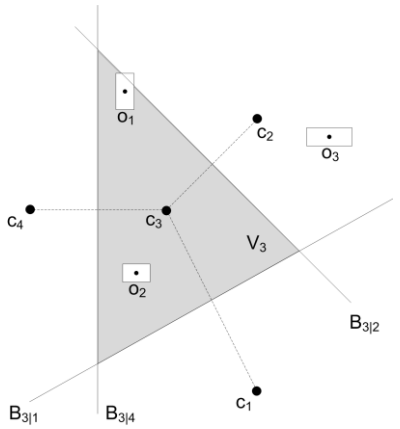

Figure 4. Construction of Voronoi cell for cluster c_3

Compute Voronoi diagram for $C=\{c_1, ..., c_m\}$
for all $c_j \in C$ **and objects** o_i **do**
  if MBR_i completely inside $V(c_j)$
    then object o_1 is assigned to cluster c_j
for all unsigned objects and clusters c_p, c_q
  if MBR_i on the same side of $B_{p/q}$ as cluster c_p
    then Remove c_q from CC_i
    */*candidate clusters*/*
for all remaining candidate clusters calculate ED

Figure 5. The Voronoi pruning algorithm

III. SEGMENTATION OF DATA SET AREA

In the SDSA method the data set area is divided into small segments. The segments are parts of the total data set area as shown in Figure 6. All segments have the same size, and they are rectangular. Only the objects in one segment are observed and paired up with clusters from a given segment and its neighbouring segments. Thus, the number of object and cluster observations is decreased. This method can be combined with all existing pruning methods such as UK-means, MinMax pruning and Voronoi cell pruning. Experiments showed that the SDSA method combined with other pruning methods speeds up the clustering process (approximately 2.5 times), depending on the number of clusters and objects. Improvement of the clustering process is reverse proportional to the size of the segments. If the segments are smaller, the clustering process is more effective. By decreasing the size of the segments, the number of observed object cluster pairs is decreased, as shown in Figure 6. Figure 6a shows an entire data set area C, and in Figure 6b the data set area is divided into four small cluster segments S_{SDSA}. Each segment is divided into four smaller segments. 16 small segments S_{SDSA} are shown in Figure 6c, and that is the final number of segments in this paper. Figures 6d and 6e show enlarged areas with objects inside them.

For 1600 objects and 64 clusters, there are 102400 object cluster pair calculations. If the SDSA method is used, the data set area is divided into 16 smaller segments S_{SDSA}, and the clusters area C is divided into 4 small areas C_{SDSA}. The average number of objects in one segment is 100, and the average number of clusters is four. Each segment is observed separately. The number of observed objects is 100, the number of observed clusters is 16 and the number of segments is also 16. Thus, the total number of object cluster pair calculations is 25600, which is four times less calculations. In this case, there is no need to check all of the clusters, but only the clusters which are near and in the surrounding area. All the remaining clusters are pruned for all objects inside the area. To

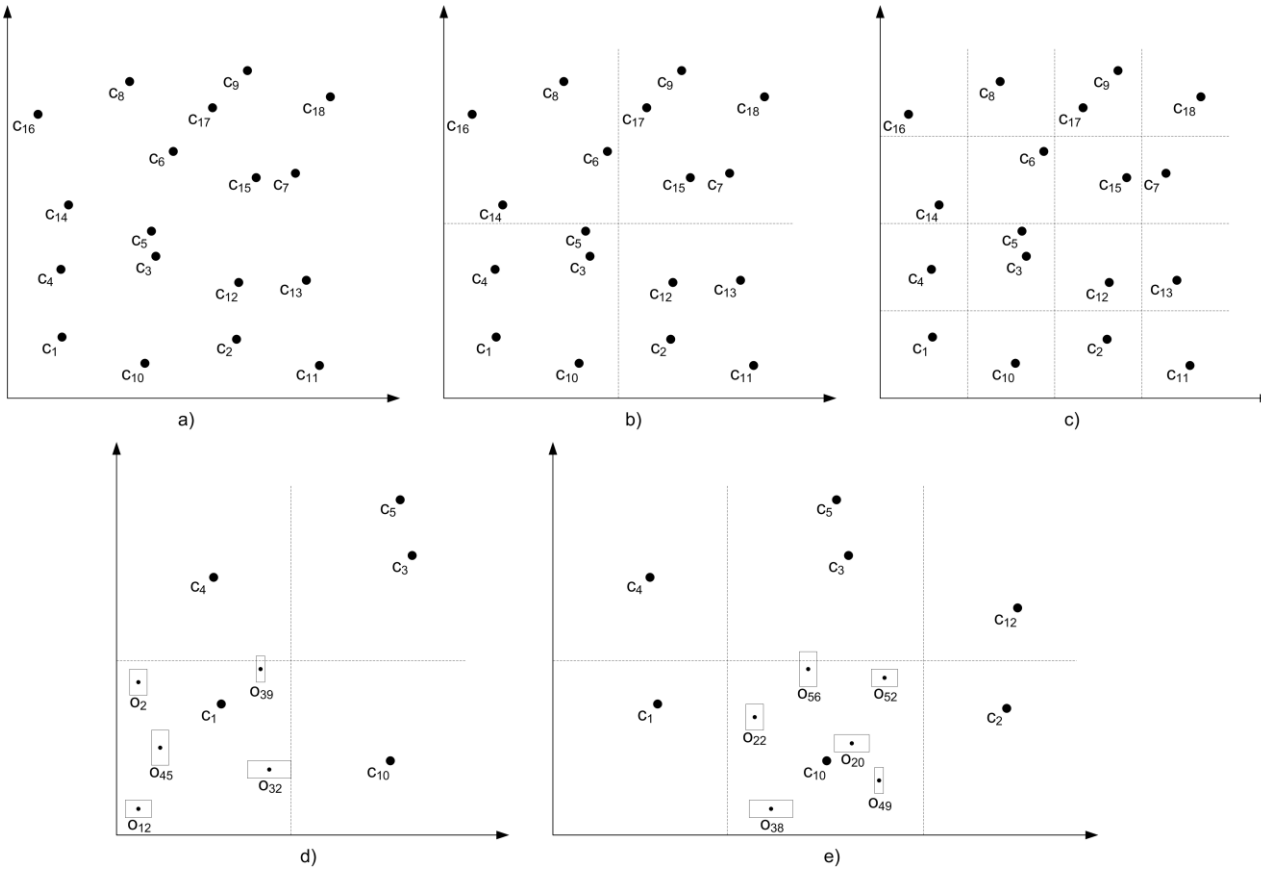

Figure 6. Process of segmetation

conclude, SDSA pruning decreases the total number of calculations by four times, in this case. Decreasing the total number of calculations is proportional to the decreasing of clusters in an area. However, the segmentation has size limits, which are dependent on the number of clusters and their positioning. The segments must be surrounded by clusters, and if the number of clusters is high, the segments can be very small, speeding up the clustering process. If the number of clusters is small, the number of segments is also small, and the execution time improvement is a maximum of 2.5 times.

The SDSA pruning algorithm is shown in Figure 7.

for all area of interest (segment)
  for all distinct c_p, $c_q \in C_{SDSA}$ **do**
    if $MBR_i \in O_{SDSA}$ on the same side of bisector $B_{p/q}$ as cluster c_p
      then remove c_q from Q_i
    elseif MBR_i on the same side of bisector $B_{p/q}$ as cluster c_q
      then remove c_p from Q_i

Figure 7. The SDSA pruning algorithm

IV. RESULTS OF THE BASELINE EXPERIMENT

The data set of *n* objects is generated with their corresponding uncertainties represented by PDF and bounded using MBR. All objects' locations are positioned in [0,100] x [0,100] 2D space. The MBR generated have a random side length for each object, but are bounded with a maximum length of 10. For each object the MBR is divided into a $\sqrt{s} \cdot \sqrt{s}$ grid, where *s* is the number of samples taken per the object's probability density function. The probability for each cell is randomly generated and the sum of all probabilities must be equal to 1. All of the objects are randomly positioned in space. For this data set, the initial cluster centres are chosen uniformly from 2D space. The basic data set is represented in Table 1. Each experiment is repeated 20 times to get a uniform execution time. The experiment results are compared, to ensure that each method has the same clustering results. All of the methods are implemented in MATLAB 7.0 and carried out on a PC with a processor Intel Core(TM) 2 Duo CPU Mobile 2.00GHz, and 1.75GB of main memory.

TABLE I. BASIC DATA SET

Parameter	Description	Value
n	number of uncertain objects	10000
k	number of clusters	49
D	maximum side length of MBR	10
S	number of sample points	196

Through these experiments, it is shown that different clustering methods have the same results, but with various execution times.

A. *Basic parameter experiments*

The first experiment is conducted with the parameters shown in "Table 1". The results are shown in "Table 2".

TABLE II. BASIC DATA SET EXPERIMENTAL RESULTS

Method	Execution time (s)
MinMax pruning	843,92
SDSA - MinMax pruning	828,74
Voronoi pruning	742,12
SDSA - Voronoi pruning	631,30

In Table 2, the execution times are given in seconds, and paired up with their methods. It is obvious that both SDSA methods give better results than the basic methods. From Table 2 it is visible that our SDSA – MinMax pruning method has a shorter execution time than the basic MinMax pruning method. It is the same with SDSA – Voronoi pruning. In the Voronoi pruning method, the execution time is longer than with SDSA – Voronoi pruning.

B. *Experiments with various numbers of objects*

In these experiments, various numbers of objects were used, but other parameters retained the basic values. Experiments started with 5000 objects and ended with 40000. The experiment results are shown in Figure 8.

Figure 8. Experiment results for various numbers of objects

It is obvious that for a small number of objects (less than 5000) the segmentation of the data set area has a minor execution time improvement on the basic methods, because the segmentation process has an influence on the total execution time. But, for a large number of objects the segmentation process has a major influence on the total execution time, and the execution time is improved. The execution time ratio of MinMax pruning and SDSA - MinMax pruning is shown in Figure 9.

The ratio for Voronoi pruning and SDSA - Voronoi pruning cores method is shown in Figure 10.

C. *Experiments with various numbers of clusters*

In this experiment, the number of clusters *k* is varied from 16 to 144 with basic values for other parameters, as shown in Figure 11. Figure 12 shows the execution time ratio of MinMax pruning and SDSA - MinMax pruning.

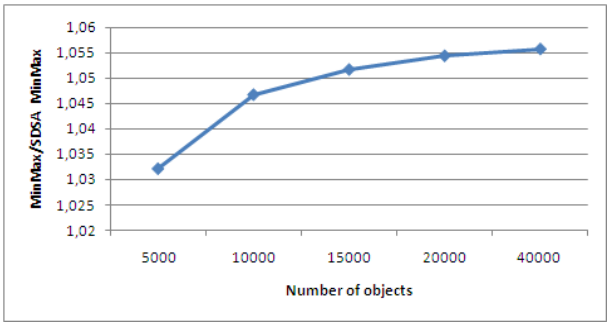

Figure 9. MinMax pruning and SDSA – MinMax execution times ratio for various numbers of objects

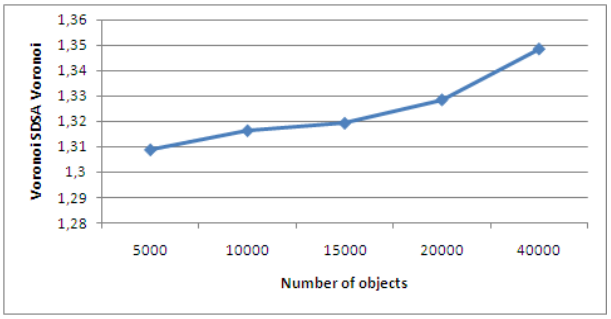

Figure 10. Voronoi pruning and SDSA – Voronoi execution times ratio for various numbers of objects

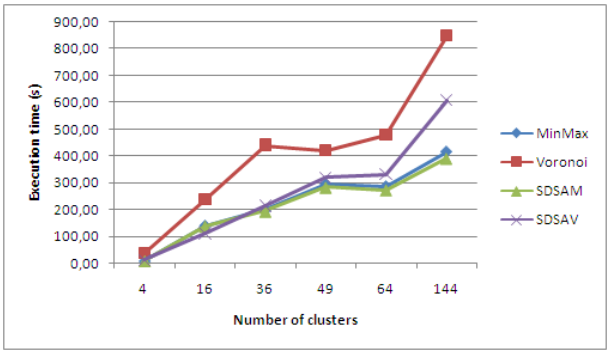

Figure 11. Experiment results for various numbers of clusters

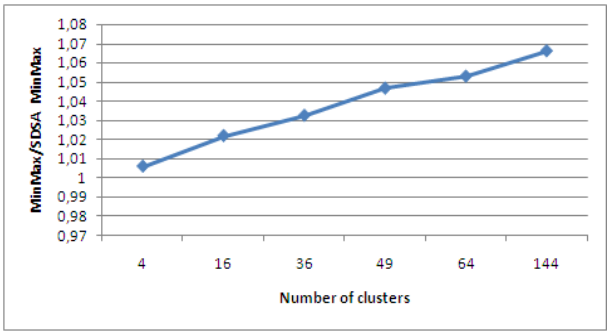

Figure 12. MinMax pruning and SDSA – MinMax execution times ratio for various numbers of clusters

The ratio for Voronoi pruning and SDSA - Voronoi pruning cores method is shown in Figure 13.

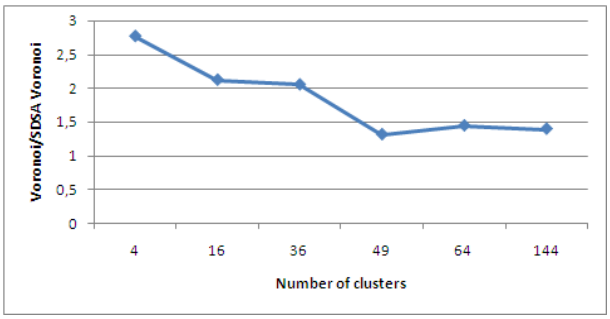

Figure 13. Voronoi pruning and SDSA – Voronoi execution times ratio for various numbers of clusters

V. Discussion and Conclusion

In this paper, different clustering methods are shown and it is experimentally confirmed that all have the same results, but with various execution times. Three methods, each with a different approach to solving the problem of clustering uncertain data, are explained. It is shown that the SDSA method, combined with these methods, speeds up the execution time of the original methods. Most of the execution time is spent on the ED calculations, because the numerical integral needs to be calculated. The objective of all the methods is the avoidance of ED calculations. However, all ED calculations cannot be avoided. Here lies the advantage of the SDSA method. This method reduces the number of object cluster observations, improves the pruning process and reduces the execution time. This paper uses the SDSA method with sixteen segments. In this case, the observed data set area is reduced by 75% in the outer segments, and by 45% in the inner segments.

The aim of this paper has been to analyse the implementation of the SDSA method in the clustering of uncertain data and the introduction to our future work. In our future work, the algorithm for segmentation will be improved, for optimal calculation of size and the number of segments, according to the number and position of the clusters. Using this algorithm, the execution time will be reduced even more and in that way will improve on the usefulness of finding uncertain objects in distributed databases. Furthermore, each segment can be independently observed, providing the possibility of a parallel execution. In our future work, we will try to implement a parallel SDSA method.

Abstract - Clouds have emerged as a new paradigm to access compute, storage, and networked resources in secure and cost effective manner. Their major benefits are seen in the commercial domain with its key features such as on-demand and more flexible resource provisioning, pay per use, and customized application environments. Also research communities such as High Energy Physics (HEP), Biology, and Neuroscience are investigating the applicability of Clouds, with their strengths and weaknesses in scientific environments. In this paper we will show that in scientific environments there are certain areas where cloud services should be exploited to support the challenging e-Science requirements. Among them are, support for virtual communities, dynamic service and resource discovery, identity and resource federation, and access to data catalogues. The Grid community has actively contributed to address some of these issues, thus we propose to reuse existing efforts to complement Cloud services with Grid computing best practices, production services, and experiences, including standardization. In this paper we will provide guidelines of how to realize multi-cloud federated deployments based on a survey of existing Grid technologies in context augmenting it with lessons learned gained in scientific environments. The contribution focuses on the areas of compute, data, information, and security. We will also show potential benefits that scientists can gain by adopting proposed solutions in cloud-based deployments.

I. INTRODUCTION

Scientific computations are no longer a domain only for High Energy Physics (HEP), computation biology, or climate modelling. Nowadays it becomes an every-day tool used even in social sciences and humanities that have been traditionally not very compute intensive. With the increasing popularity of the computational methods also the demand for compute, data, and networked resources increases. With broadening application of the computer-supported methods we also see changes in the resources demanded and paradigms used. Some of them cannot be easily satisfied by HPC/HTC resources offered by the research computer centres (e. g. dynamic expansion of compute resources into the unlimited region). It is also not practical nor economically justified for the new communities to create their own computer centres or to perform over-provisioning of resources for rare peak times in the research life-cycle. Therefore existing computing centres consider outsourcing resources e. g. by increasingly using Clouds. By this we are partly motivated by the success of the commercial public clouds, and partly to profit from the effect of scale and consolidation of resources.

Furthermore, the paper is also motivated by the work within the e-Infrastructure Reflection Group (e-IRG) that puts it this way: While academia has thus far approached distributed computing infrastructures using the Grid, useful for its federating ability and collaborative approach, the introduction of the new "Cloud Computing" paradigm demands a fresh assessment and attitude [1]. Cloud computing offers compute, data and networked resources based on the pay-per-use, on-demand, and prudent manner. In the current situation scientists want to, however, access different resources (HPC/HTC, Storage, clouds) offered by different providers (research computer centres or even commercial clouds). This is currently hard to achieve, due to a massive amount of existing computing and data resources, proprietary interfaces, and in-compatible authentication and authorization systems existing in public and private cloud offerings. The problem is even harder to solve for the cross-boundaries research endeavours where representatives from different communities are active.

To some extent the situation is similar to the situation that lead in the past to emerging of Grids [2], when it was required to have seamless access to distributed resources via standardized interfaces across multiple administrative and geographical boundaries. In this paper we propose to capitalize on these experiences and to work towards an easy-accessible federation of heterogeneous resources. Through such a federation, scientific virtual communities could actively collaborate their results and provide access to distributed resources. As we mentioned earlier, that Grid communities have already invested ample amount of research to solve similar kind of challenges, and to establish unified view and access methods to federated resources. The clouds are, in our opinion, on the verge of establishing *federated clouds* i. e., to overcome the boundaries between different cloud providers and deployments. Thus we believe that the current cloud solutions could profit from the Grid experiences by

incorporating the well-established and production-ready solutions from compute, data, security, and information system areas. By considering its strengths, we propose to reuse a set of existing middleware technologies and standards when implementing or deploying cloud solutions. In this work our analysis is based upon the technologies represented within the European Middelware Initiative Project (EMI) [3]. The European Middleware Initiative is a close collaboration of the three major middleware providers, ARC [4], gLite [5] and UNICORE [6], and other specialized software providers like dCache [7] working towards a unified set of Grid middleware distributions. Furthermore, we will also put an emphasis on the set of available standards in the Grid domain which could bring benefits in terms of offering an easy access to larger, heterogeneous, virtual resources.

After surveying related work in Section II, our analysis of Grid services and standards applicable to support the vision of federated clouds is given in Section III. Where we list the existing technologies offered by EMI compute, and related standards that can be used to federate cloud computing VM access interfaces. In a similar manner the following sections IV, V, VI will analyze data, information, and security areas. We conclude our paper in Section VII.

II. Related Work

Since the Cloud computing paradigm emerges in the context of e-Science infrastructure (aka Distributed Computing Infrastructures (DCI)), many publications and reports provide high-level statements like "including specialized portals hiding the certificate complexities of Grids as well as the possibility of learning from the Cloud virtualization approach." [8]. Another report [1] "Seeking a way to combine best aspects of the Grid and Cloud Computing requires resolving technological and policy level conflicts between two paradigms that have started based on very different requirements, use cases and basic assumptions." Finally, statements like "Europe should also build its innovative advantage in key areas through reinforced e-Infrastructures and through the targeted development of innovation clusters in key fields. It should develop an EU-wide strategy on cloud computing notably for government and science" were also published [9]. Despite the existence of such high-level publications we can conclude that no clear roadmap and vision for cloud developments in science really exists today.

An effort of clarification of and distinction from clouds was undertaken by the Grid community. The Grid paradigm started to evolve more than a decade ago with a publication by Foster et al [2]. It is thus appropriate to revisit Fosters latest views on how Grid and clouds are related. In [10], Foster compares both approaches side-by-side using different model perspectives (i. e., business, architecture, resource management, data, programming, application, and security). We agree with conclusion that clouds and Grids share a lot commonality in their vision, architecture, and technology. But it provides only several general overviews and a few concrete examples in context based on a few existing distributed systems developments available (mostly Globus [11]). In contrast, this paper focuses thus more on different approaches and techniques that contributed significantly to the success of Grids i. e., information model, broker, attribute authority, etc. and where existing developments are available provided by the EMI. It makes thus sense to survey related studies for this contribution with a focus on those initiatives that aim to reuse concrete existing Grid technologies and standards in cloud development activities.

Lezzi et al, provides in [12] a description of how the VENUS-C cloud platform can be used with e-Science applications. Within this architecture platform Grid standards such as OGSA-BES and JSDL are re-used for job management. In contrast to this contribution, our paper extends this view to other approaches beyond job management covering also information, security, and others. StratusLab [13] is another project that develops cloud technology primarily targeting the scenarios for offering Grid interfaces to virtual machines. The major breakthrough in this project is the planned support of Grid-based authentication and authorization mechanisms that is in-line with the finding of this paper. It allows users with X.509 credentials to seamlessly launch and monitor virtual machines. Apart from security area, the StratusLab approach tackles also other areas we mentioned, but being based on rather proprietary interfaces. In contrast, this paper aims to not only propose existing developments in context, but also suggests open standards in various areas (e. g., accounting, information, etc.). Finally, a survey of related approaches would be not complete if we not question the overall approach of "developing new clouds" with existing technology that still needs to be extended to meet the cloud users need. Instead, it might be wise to think about a complementary approach meaning "Integration of existing grid layers with the on-demand delivery model typical of commercial Clouds" as highlighted in [14], that paper tackles the question how e-Infrastructure can emerge to satisfy the needs of the emerging European Strategy Forum on Research Infrastructure (ESFRI) projects. For example, Di Meglio et al. [15] compared Grid and cloud integration scenarios with a generic overview of the number of combinations through which resource centers can effectively combine and offer both paradigms altogether. The paper also articulates the implications on several standards and, analyzed how

much overhead on technologies in terms of costs and implementation is required to provision both Grid and cloud interfaces at the same time. In contrast, this paper rather focuses on the different technical areas that are faced during integration of Grids and clouds instead of high-level combinations possibilities.

III. Compute Services

In distributed systems compute service is a capability offering interfaces for accessing CPU cores, including the management of the running applications life-cycle. In clouds, generally, we consider compute area is a package of virtual machine management and monitoring, resource allocation, and scheduling capabilities. The VM Management layer hides the complexity of hypervisor interaction, which includes dispatching VM to the appropriate physical hosts, and releasing resources after use.

The current landscape of cloud solutions is shaped by increasing number of the open source cloud solutions and public offerings of this service. With these advancements, there are upcoming challenges for scientific communities when it comes to interact with multiple of these kinds of cloud sites. This is more evident with virtual communities, each of which may consist of cloud endpoints supporting nonstandard interfaces. In an ideal case, a user should be able to submit the VM execution request to any of the sites available within a community, without the need to account for special properties of the particular cloud deployment. Once we contemplate on a scenario of VM run across different cloud platforms, therefrom we see two significant requirements: resource requirements description language, and remote interface managing and monitoring the life-cycle of the VM.

Under the domain of Grid computing, there have been similar challenges of offering compute resources to the virtual organizations. To deal with such requirements, EMI adopts broker-based technologies where scientists run jobs on hybrid Grid platforms. Within the EMI portfolio, WMS (Workload Management System) [16] suite allows the distribution and management of jobs to multiple, disparate computing resources. In a likewise manner, we could extend and apply this solution to enable scientific virtual communities forming a federated inter-cloud infrastructure. This will not only enhances the adoption in cloud communities, but also help resource centres willing to integrate their Grid and clouds offerings more seamlessly.

In order to federate heterogeneous clouds, standard compliance significantly reduces much overhead of end user clients interacting with diversified cloud interfaces hosted on an infrastructure [17]. From the past experiences, Grid community faced interoperability challenges in the establishment of the production e-Infrastructures [18], [19], [20], [21] wherein sites expose proprietary job management interfaces. In which the implied use of standards came to fore as a resolution for integrating multiple computing sites part of pan-continental initiatives. By having the experiences from infrastructure integration concerns, we see Grid "compute" standards such as OGSA-BES [22], and JSDL [23], became a viable choice for service implementers. As a matter of fact, these standards have been derived and adopted by major production Grid middleware providers [24], [25], and [26] to cater job management and monitoring scenarios. The standardization process of these interfaces then assured that broad agreements have been achieved in terms of the functionality it covers. Inspired by this concept, we can thus treat cloud VM as a Grid Job, which implies VM execution through the Grid standard execution service. In our proposal we envision the adoption of Grid standard interfaces to the cloud VM management layer, will positively influence the initiatives towards the vision of realizing inter-cloud infrastructure services and unified client tools. This approach will also invite the Grid users, who are early clouds adopters, to launch their customized VMs as execution environments using standards supported Grid clients.

IV. Data Management

Many experts envision data-oriented science and computing as the most important paradigm of the e-Science in the coming years [27]. In fact the data volumes collected by the scientists grow in sizes and complexity. As a result of a distributed process of data collection and creation, the data are naturally distributed. The heterogeneity and distribution of these resources, however, make it hard to efficiently access and analyse the data collected by different communities, in different storages, in different points in time (using various data formats and data access methods).

Current cloud storages like Amazon Simple Storage Service (S3) [28] or OpenStack Swift [29], they offer access to distributed data and some replication functionalities but all that is confined within one cloud infrastructure. From the scientific perspective, this is a huge drawback leading to known problems such as "science data silos" that are not conveniently accessible by the broader scientific community. Hence, to be able to cope with the large amounts of distributed data we need to provide the users with a means to access them in an abstract way which hides the underlying complexity. The users usually do not care where the data are stored, they want to simply access or actually extract information from the data.

This known fact led to establishment few Grid technologies that are able to create federated data storages or data Grids. The EMI Portfolio includes few such a solution. Probably the most prominent example

of a storage technology in Grids is dCache [7]. dCache offers a transparent access to disk-and tertiary (tapes, etc.) storages and allows for migration and replication of the data between physical locations without affecting the end-user. All the technical details are hidden from the user behind well-defined data access interfaces Storage Resource Manager (SRM) [30], http, WebDAV.

Similar functionalities (aggregated view and access to distributed disk storages) are also offered by: Disk Pool Manager (DPM) [31], StoRM [32] all three offer Storage Resource Management interface. The role of SRM in typical Grid ecosystem is to support basic data-related operations (file transfers and management, directory manipulation tools, replication and archiving data on mass storage systems). These functions are performed in a transparent way, for instance SRM implements protocol negotiation which allows to make files accessible from one physical location to other without any user intervention.

Another important aspect of distributed data management is the metadata management. Grid also provide tools for that, in this regard EMI offers a flexible metadata manager: AMGA [33]. AMGA enables annotation of data items with key-value metadata pairs and search functionality. The annotation is performed out-of-storage, that it is easily possible to use AMGA at federation level to create and describe collection of data resources independent from their physical location.

Above-mentioned Grid services and standards help to "merge" all different kind of data resources located within different infrastructures, allowing to virtually federating the data. The way a cloud data federation could be established with help of Grid services and standards would be to simply add an integration layer between currently distributed cloud storages and an inter-cloud instance of dCache or AMGA providing a unifying view of all the data and metadata resources. The interfaces of Storage Networking Industry Association (SNIA) such as Cloud Data Management Interface (CDMI) [34] might be useful in this context. Secondly it would be advisable to foster the usage of data access standards: SRM is one of the examples that need to undergo an evolution to be simpler if it should be fully used in cloud setups. However, it remains an excellent basis to start from. To reduce the hurdles of accessing different storages such an interface is needed.

V. INFORMATION SERVICES

Information services in clouds are the set of components to discover and publish capabilities and usage of the underlying resources. The information exposed by such services consumed for scenarios such as service availability, service discovery, service monitoring, and resource usage. Existing open source cloud solutions such as OpenStack [35], Open-Nebula [36], Eucalyptus [37] individually provides their own mechanisms of exposing resource information. Considering these solutions deployed on different sites as a part of an infrastructure, it will pose a plethora of requirements to form a consistent structure of representing such information. In order to unite resource information per se and the process of aggregation and register, we may require developing a set of components to perform functions mentioned earlier.

Again it is possible to learn from Grid experience in this context, since Grids are spanned over distributed regions and already deployed using different middlewares that are combined to form a collection of resources emitting information in a consistent manner. Whether it be a HPC or HTC based resource, the high level infrastructure administrators conveniently fetch an overview of different types of resource information and its key capabilities, depending on the site policies they can also further obtain a fine grained usage and accounting information. For catering such requirements, EMI produced a set of information components, which are mature and developed over years, and used in global-scale production infrastructures such as EGI [38].

Complete and correct information model is a basis for any type of service registry and information service. In the above mentioned information components, we see an urgent need to place an information model for information exchange purposes. Clearly the back-end model is also required for usage service as a foundation for integrating and uniting accounting information in an open, research based infrastructures. Similarly, Grid community published GLUE 2 [39] information model standard and Usage Record specification [40]. GLUE 2 information model provides an enriched representation of compute, and storage resources. These both kinds of resources are also present in cloud environments. In terms of GLUE 2 application for clouds, we need to perform minor extensions in terms of concepts and attributes to introduce entities peculiar to Virtual computing environments.

In modern distributed clouds, where federation is paramount, the services and resources are behaving in transient manner: being added to and removed from the federated infrastructure dynamically. Hence an infrastructure service registry which must reliably depict the status of cloud service's information is required. The lack of common service index drives the need of new service registry to perform the look-up and discovery in a unified manner. However, open source cloud solutions are already equipped with local service registries, which are used for internal management respective specific to the cloud middleware. As such, considering an infrastructure composed of different cloud distributions, local registries will not be useful for combining heterogeneous entities. EMI as a unified Grid middleware distribution supports the federation of Grid services through a common service registry called EMIR [41]. EMIR has been designed to index Grid services; furthermore it supports mechanism to federate distributed registry nodes in a robust manner. It supports a standardized GLUE 2 model to represent the service endpoints and offers a lightweight RESTful API to make registrations and query. In order to share usage

information among multiple clouds, the sites need to communicate its resource accounting and usage information in standard format across the range of community based infrastructures. In the domain of Grids, OGF produced Usage Record (UR) specification [40] encapsulates the thorough semantics of accounting information model specialized for Grid resources. Specifically, in EMI we extended Usage Record specification with an emphasis on support of virtual communities, and the usage of storage services. Along with OGF UR specification and EMI extensions we propose, are very much applicable to realize federated accounting infrastructure for heterogeneous and distributed cloud resources.

VI. Security

Security is probably the hardest and most important problem that needs to be solved on the way towards cloud federation. It is a cross-cutting concern influencing all other aspects of the federation. Current situation in which each infrastructure provider use different authentication and authorization solutions constitutes a major hurdle for a seamless easy access to distributed resources. Long year effort of the Grid community lead to (almost) standardized way of accessing Grid resources. Grid uses certificate-based access to provide high-security on one hand and usage of resources offered by different providers on the other (credentials are not bound to a particular infrastructure).

Particularly in conduct of a harmonization effort EMI decided to use VOMS [42] as a product representing an Attribute Authority (AA) which releases signed security credentials with information beyond pure identities. VOMS authenticate user based on her Grid Certificate and issues X.509 attribute certificates and, more recently, Security Assertion Markup Language (SAML) authentication tokens. Second phase of accessing Grid resources is to derive authorization decisions. Within the EMI landscape this can be done by ARGUS [43]. It is responsible for generating consistent authorization decisions across geographically distributed Grid services. The internal ARGUS policies are described in a standardized way with help of eXtensible Access Control Markup Language (XACML) [44]. The interesting aspect of this security solutions proliferating in Grid is the notion of trust delegation. It allows authorizing access to data and computing resources not only for human users but also for other services acting on behalf of an end-user

Nevertheless the final report of the 7th e-Infrastructure concertation meeting indicated clearly that certificates are complex too and the use of clouds can be the answer to “Find a way to alleviate certificates” [8]. It is a safe bet to say that the certificate-based authentication will not gain broad acceptance as a cloud access method. Thus the Grid services are not directly applicable as a building block for cloud federation. Some integration effort need to be undertaken in order to provide unified authentication and authorization methods. It is hard to assess the exact amount of work that need to be done to achieve such integration. Pragmatically in many cases it is not trivial at all. The commercial cloud solution providers might be reluctant to undertake any modification of their software. Although, even commercial providers can profit from the unification of security solutions, this may open opportunities for new communities. Most of the available open-source cloud solutions follow a modular design allowing to extend or substitute infrastructure components. In fact OpenStack extracted their AA and created a stand-alone product [45], this can be interpreted as an “expression of will” to work on flexible authentication and authorization.

Also EMI become aware of the limitations of the certificate-based authentication in some cases. Thus an effort towards the use of more standardized interfaces in this filed has been undertaken, leading to a Security Token Service (STS) library. This can be used as a trusted source of security tokens derived from yet other tokens. STS basically translates “everything to everything”, allowing to convert results of any given authentication method to any given authentication token. Clearly STS could be used to integrate clouds infrastructures with common authorization service (on federation level).

VII. Conclusion

In this paper we convey a vision of federated clouds. We envisioned distributed compute and data resources unified, and providing easy, transparent access to the research users. We also pointed out that the vision could be realized by using Grid services and standards to bridge the gaps between current cloud offerings (be it commercial or private research clouds). Throughout the discussion we try to avoid to make a claim that one technology (Grid or cloud) is better than the other since there is much potential for being complementary to each other. Grid is around for many years thus it indeed provides some useful, production-ready solutions. We provided the reader with some pointers showing applicable services and standards, and benefits of using them.

On the other hand, we also identified gaps in the federated clouds which cannot be bridged by just the integration of existing services and standards but rather require a common effort to extend them, and also to shape emerging use cases into the standardized interfaces and models.

ACKNOWLEDGMENT

This work has been generously supported by the EC funded EMI Project under grant agreement INFSO-RI-261611. We owe a debt of gratitude to Evangelis Floros from GRNet, Michel Drescher from EGI, and the members of EMI Virtualisation and Cloud Task force for their participation in valuable discussions.

The efficient use of e-Infrastructures requires researchers to combine Grid, High Performance and Cloud resources in a way that allocates rationally the physical resources among the research tasks and activities and minimizes the movement of data and the waiting times. The high complexity of the computing infrastructure available for researchers underlines the importance of clear understanding of the security treats and devoting sufficient resources for their mitigation. In Eastern Europe there is a tradition of joint operations and usage of Grid and High Performance Computing resources for the needs of research and education. In this paper we identify some important use cases of combined usage of Grid and Cloud resources and consider the security treats and attack vectors that should be the prime target for investigation and mitigation in this context. By leveraging our experience from the so-called Security challenges in the EGEE Grid infrastructure, we identify steps and best practices that could decrease the risk from penetration by random as well as determined attackers and outline services that could bring down the overall security risks.

I. INTRODUCTION

The Grid is a computational infrastructure which ensures transparent access to geographically and institutionally distributed computational resources and data. The Grid has been studied extensively during last two decades, here we refer to some works of Foster and Kesselman, and also to description of the largest grid (the EGEE grid) [2, 3, 4, 5]. Ian Foster and coauthors gave a three point checklist [5] to help determine what the Grid is, and what is not:

1. The Grid coordinates resources that are not subject to centralized control,
2. The Grid uses standard, open, general-purpose protocols and interfaces, and
3. The Grid delivers non-trivial qualities of service.

Recently, "Cloud" became very popular buzzword. Although Cloud Computing sounds like a new technology, it has intricate connection to Grid Computing paradigm. There is a little consensus on how to define the Cloud and here we accept the Foster definition in [6]: "*A large-scale distributed computing paradigm that is driven by economies of scale, in which a pool of abstracted, virtualized, dynamically-scalable, managed computing power, storage, platforms, and services are delivered on demand to external customers over the Internet.*"

In the same paper, [6], Foster et all compare Grid and Cloud and conclude that only point 3 from above checklist holds true for Cloud computing, but neither point 1 nor point 2 are valid for Clouds.

The common characteristics of Grid and Cloud are

- Utility computing
- Aggregation of heterogeneous resources
- Access transparency for the end user
- Re-configurability
- Service negotiation based on Service Level Agreements
- Capacity provisioned on demand
- Continuous availability
- Single sign on

This comparison of Cloud and Grid helps us understand the security issues which arise when using both of them as part of a scientific application.

II. TYPICAL USE CASES FOR COMBINING GRIDS AND CLOUDS

The attractiveness of Clouds from economical and managerial point of view and the established nature of Grid technology in the area of e-Science underline the necessity to consider the most practical use cases for combining the use of Grid and Cloud resources for scientific computations in order to study their security aspects. One of the most basic cases would be when an infrastructure provider, e.g., a university, can use (lease) Cloud resources to provide Grid services, demanded by its users. It is technically feasible to provide all the worker nodes for a Grid cluster using cloud resources. The storage resources of a Grid site can also be provided from the Cloud. Since some Grid middleware has a requirement for proper forward and *backward* DNS resolution it would be difficult to provide the service nodes for such a cluster from Cloud resources. From point of view of

users there will be no difference to their normal workflow. It is also possible for only part of the resources of a cluster to come from Cloud worker nodes. Such a solution would be beneficial if there are certain jobs that are sensitive to waiting times in the queue. The infrastructure provider can utilize a small pool of Cloud-based Worker Nodes to ensure quality of service, benefiting from elasticity of cloud resources.

A virtual organization can use the cloud to deploy and host service nodes, e.g., web servers or databases. Service nodes that run specific Grid middleware, which is not necessary for all the members of the VO, are good candidates for cloud deployment, since they can be managed by the interested subgroup of members of the VO.

From economical point of view it may be interesting to consider utilization of the free capacity in the Grid resources from cloud applications. Since there are specific security and policy constraints about how such resources can be utilized, they may be hooked-up as a back-end to some pre-approved cloud-based industrial applications.

One use case that is more technical in nature is that some Grid services may be efficiently put on the Cloud to benefit from the "elasticity" of Cloud service provisioning. For example, the so-called BDII is a service which would benefit from authomatic load-balancing, because occurances of high load on the BDII are generally unpredictable and have strong adverse effect on correct functioning of all Grid.

We also outline the possibility of a small or medium enterprise that needs technical and scientific support from a research organization that has Grid resources in order to develop their industrial application. In such case the computational and storage resources are initially supplied from the Grid while the production utilization will be transferred to the Cloud. In this case it is important to use frameworks and APIs that would facilitate this transition.

III. Security aspects

We summarize below the types of authentication, authorization and accounting mechanisms that are used in Grids and Clouds.

III.1. Security management in Grids

The cornerstone of the security management in Grid is the notion of the so-called Virtual Organization (VO). Users are organized in Virtual Organisations, which share resources. Many institutions may provide the resources of the virtual organization and these resources become available to all members of the organization. It is important to note that only the biggest virtual organizations, comprising of thousands of scientists, define groups inside the virtual organization and enforce the division between members of these groups and the respective job priorities. It is important to note that in most practical cases a user of the VO has access to all the data files of the VO and can not only retrieve data, but also delete data, even if the file has been created by another user.
